

Nyx

A Data-Driven Astronomical Observation Platform Using NASA Space Data
and Local Observations in Mauritius

1. Abstract

This dissertation presents the design and implementation of Nyx, a full-stack astronomical observation platform that integrates data from NASA's Transiting Exoplanet Survey Satellite (TESS) with ground-based observations captured from Mauritius. The backend is implemented in C++23 using the Drogon HTTP framework and follows a clean architecture with strict layer separation. A four-stage data ingestion pipeline queries the MAST API for target resolution and TESS observation metadata, discovers FITS data products, downloads binary light curve files, and parses them using CFITSIO into structured time-series records stored in PostgreSQL. The authentication system supports local registration with email verification and Google OAuth2, using JWT access tokens with refresh token rotation and reuse detection. The frontend, built with Next.js and Plotly.js, provides interactive light curve visualisation with WebGL rendering and supports overlay of ground-based observations on TESS data. The system exposes 25 REST API endpoints across five domains and is validated with 136 unit tests using GoogleTest. Data validation against the known exoplanet host star π Mensae confirms that the ingested TESS light curves are consistent with published transit parameters. The platform addresses a gap in existing tools by providing a single interface for target resolution, space-based data retrieval, ground-based observation management, and cross-source data comparison.

Glossary

- API** Application Programming Interface. A set of defined rules enabling software components to communicate.
- BJD** Barycentric Julian Date. A time standard that corrects for the observer's position relative to the Solar System barycentre, removing orbital motion effects from timing measurements.
- BTJD** Barycentric TESS Julian Date. The time system used by TESS, corrected for light travel time to the Solar System barycentre. Defined as $\text{BJD} - 2457000.0$.
- CAOM** Common Archive Observation Model. A standardised data model used by MAST to describe astronomical observations across multiple missions.
- CSRF** Cross-Site Request Forgery. An attack where a malicious site submits requests on behalf of an authenticated user. Mitigated using the double-submit cookie pattern.
- ETL** Extract, Transform, Load. A data pipeline pattern for ingesting data from external sources, transforming it into a target format, and loading it into a database.
- FFI** Full-Frame Image. A TESS data product capturing the entire field of view of a camera at 30-minute (primary mission) or 10-minute (extended mission) cadence.
- FITS** Flexible Image Transport System. The standard file format in astronomy for storing images, spectra, and tabular data. Defined by the IAU FITS Working Group.
- Flux** The amount of light received from an astronomical object per unit area per unit time, typically measured in electrons per second (e^-/s) for space-based photometry.
- HDU** Header Data Unit. The fundamental building block of a FITS file, consisting of an ASCII header followed by an optional data array.
- JWT** JSON Web Token. A compact, URL-safe token format used for stateless authentication. Contains encoded claims signed with a secret key.
- Light Curve** A time-series of flux measurements for an astronomical object, used to detect transits, eclipses, and variability.
- MAST** Mikulski Archive for Space Telescopes. NASA's primary archive for ultraviolet, optical, and near-infrared astronomical data, hosted by the Space Telescope Science Institute.
- OAuth2** Open Authorization 2.0. An industry-standard protocol for delegated authentication, allowing users to sign in via third-party providers such as Google.
- PDCSAP Flux** Pre-search Data Conditioning Simple Aperture Photometry flux. TESS flux values corrected for systematic errors such as spacecraft pointing jitter and thermal variations.

Photometry The measurement of the intensity of light from astronomical objects. Differential photometry measures brightness changes relative to comparison stars in the same field.

RAII Resource Acquisition Is Initialisation. A C++ idiom where resource lifetime is tied to object lifetime, ensuring deterministic cleanup via destructors.

REST Representational State Transfer. An architectural style for web APIs using standard HTTP methods (GET, POST, PUT, DELETE) with stateless request-response semantics.

SAP Flux Simple Aperture Photometry flux. Raw flux values extracted from TESS pixel data by summing counts within a defined aperture, before systematic correction.

SPOC Science Processing Operations Center. The NASA Ames facility responsible for processing raw TESS data into calibrated light curves and target pixel files.

SSE Server-Sent Events. A unidirectional HTTP-based protocol for pushing real-time updates from server to client over a persistent connection.

SSR Server-Side Rendering. A web rendering strategy where HTML is generated on the server rather than in the browser, improving initial load performance.

TESS Transiting Exoplanet Survey Satellite. A NASA space telescope launched in 2018 that surveys nearly the entire sky for exoplanet transits using transit photometry.

TOI TESS Object of Interest. A star identified by TESS as hosting a candidate transiting planet, pending confirmation by follow-up observations.

TPF Target Pixel File. A TESS data product containing the raw pixel data for a small region around a target star, used for custom aperture photometry.

Transit The passage of a planet in front of its host star as seen from the observer, causing a measurable dip in the star's brightness.

2. Introduction

2.1. Background

Modern astronomy is mostly a data science field. The amount of data from space missions has been growing at an exponential rate in the last two decades. Missions like the Kepler mission and its successor the Transiting Exoplanet Survey Satellite (TESS) have contributed to this growth. The Kepler mission, which launched in 2009, observed 150,000 stars for four years and led to the discovery of the first large number of exoplanets (Borucki *et al.*, 2010). The TESS mission, which launched in 2018, has observed 26 different areas of the sky for approximately 27 days each (Ricker *et al.*, 2015). TESS collects 27 GB of data per orbit, enabling high-cadence brightness measurements of hundreds of thousands of stars per orbit. All of the data collected by TESS is stored in NASA’s Mikulski Archive for Space Telescopes (MAST). MAST stores data from numerous astronomical missions, with over 500 TB of stored data as of 2024 (Space Telescope Science Institute, 2024).

The main technique that will be employed in both of these missions is the technique known as transit photometry, in which the dimming of a star’s brightness due to the presence of a planet in front of the star is detected. The data that is obtained from this method is a light curve, which plots the brightness of the star over time. The depth of the dips in the light curve indicates the radius of the planet, and the period of the dips indicates the planet’s orbital period (Winn, 2010). Furthermore, light curves can also be used to study other astronomical phenomena beyond planetary transits. Thus, the ability to analyse light curves is an essential skill within the field of astronomy.

Simultaneously, ground-based amateur astronomy has become increasingly capable of performing photometry of variable stars with the availability of affordable telescope equipment and software (Fitzgerald *et al.*, 2014). Even relatively inexpensive telescopes, such as a 130mm Newtonian reflector mounted on an equatorial mount, and even using smartphones as the cameras, it is possible to perform imaging of certain variable stars (Gary, 2007). Furthermore, organisations like the American Association of Variable Star Observers (AAVSO) and the British Astronomical Association (BAA) utilise the observations of amateurs to contribute to the understanding of variable stars and exoplanets (Conti and Conti, 2018). The observations of ground-based telescopes can help to supplement those of space-based telescopes through the ability to provide longer-term observations of variable stars, to observe periods between space-based telescope observation windows, and through the use of ground-based telescopes to confirm the observations of space-based telescopes.

However, a disconnect exists between these two data sources. The nature of the TESS observations is completely different to ground-based observations. The TESS observations are kept in FITS files, a binary file format standard in astronomy that contains 2-minute or 30-minute calibrated flux measurements (Tenenbaum and Jenkins, 2018). These files use the Barycentric TESS Julian Date (BTJD) time system to account for the movement of the TESS satellite compared to the Solar System barycentre (Eastman, Siverd and Gaudi, 2010). In contrast, amateur ground-based observations are stored as JPEG or FITS files in which the

flux must be extracted from the images, and the measurement of time uses either the UTC or Julian Date time systems. Therefore, to integrate these two data sources, the software will need to parse binary FITS files, account for differences in the time systems, deal with different noise profiles in the data, and normalize the flux measurements from each type of observation, all of which presents a data engineering challenge.

Mauritius, located at 20.3° S latitude and 57.5° E longitude in the Indian Ocean, possesses a number of geographic advantages for ground-based astronomical observations. First, its location in the southern hemisphere provides visibility of numerous astronomical objects that are inaccessible from most observatories in the northern hemisphere. Objects such as the Magellanic Clouds, the Galactic Centre, and a plethora of exoplanet hosting stars are visible from the southern hemisphere but not visible from the northern (Ricker *et al.*, 2015). Furthermore, during TESS' first year of operation (July 2018 – July 2019), its primary observation target was the southern portion of the ecliptic plane, after which it performed observations of the northern portion of the ecliptic plane (Ricker *et al.*, 2015). Second, Mauritius lies in a longitudinal gap in relation to most major observatory locations in the southern hemisphere. The majority of ground-based observatories in the southern hemisphere are located in Chile ($\sim 70^{\circ}$ W), South Africa ($\sim 18^{\circ}$ E) and eastern Australia ($\sim 150^{\circ}$ E) (Hessman, 2004). Thus, an observer on Mauritius can collect observational data during the night time when none of these three locations are observing the skies. Despite these geographic advantages for performing astronomical observations, there is currently no infrastructure for astronomical observation on the island, and no existing platform for comparing in-situ observations with data collected by spacecraft like TESS.

2.2. Problem Statement

High-quality photometric data is available from NASA's open data archives. The archives are, however, aimed primarily at professional researchers. The MAST API that NASA employs returns data in JSON format, which requires some knowledge of the domain to effectively use. To construct a query to the API, one must manually construct a JSON request that includes the relevant parameters and filters for the observation that is to be queried. The returned data is in the form of a JSON object whose column names, types, and values are returned as separate arrays (Space Telescope Science Institute, 2024). To answer a relatively simple question of interest to amateur astronomers, such as "how does my ground-based observation of a given star compare to that made by the TESS satellite?" an observer must manually query the MAST API for the relevant data, download the observations in the FITS file format, parse the file with libraries such as CFITSIO (Pence *et al.*, 2010), and plot the results with Python scripts or other software such as Lightkurve (Lightkurve Collaboration *et al.*, 2018). Each one of these steps indicates a level of expertise in Python and in the TESS and MAST APIs that acts as a barrier of entry for amateur astronomers.

Some tools are available that aim to make the process of querying the TESS satellite data and comparing it to ground-based observations easier. Lightkurve, for instance, provides a Python API that allows researchers to download and analyse light curves from the Kepler

and TESS satellites; however, as a programmatic library rather than a web application it does not allow for integration with ground-based observations (Lightcurve Collaboration *et al.*, 2018). The Exoplanet Transit Database allows amateurs to submit their observations of planetary transits, but provides no access to TESS data (Poddany, Brat and Pejcha, 2010). The AAVSO International Database also allows amateurs to submit their light curve observations, but mainly of variable stars rather than exoplanet candidates (Kafka, 2021).

There is currently no platform that integrates the following functions:

- Resolving astronomical objects by name
- Retrieval of TESS data
- Parsing of ground-based and TESS data
- Storage of data in a relational database
- API for frontend integration
- Platform for amateurs to upload their observations

This problem is not an astrophysics problem but a data engineering problem. The data exists; the problem is to build the system that appropriately ingests, transforms, stores, and retrieves the data.

2.3. Aim and Objectives

The aim of this project is to design and implement a data-driven astronomical observation platform that integrates NASA space mission data with ground-based observations captured from Mauritius.

The objectives are:

1. Design and implement a backend using modern C++ that exposes a RESTful API for synchronous operations, background job processing for long-running data ingestion tasks, and Server-Sent Events (SSE) for real-time progress updates to the frontend. The architecture should follow clean architecture principles with clear separation between domain logic, data access, and presentation layers.
2. Build a data ingestion pipeline that queries NASA’s MAST API, retrieves TESS observation metadata, discovers data products, and downloads and parses FITS light curve files into structured time-series data.
3. Implement a PostgreSQL-backed persistence layer that stores astronomical targets, TESS observations, and light curve data points in a schema optimised for time-series queries.
4. Develop an authentication and authorisation system supporting local registration with email verification and third-party OAuth2, with security measures including JWT token rotation, CSRF protection, and rate limiting.
5. Create an observation management module that allows authenticated users to record ground-based observation sessions with associated equipment metadata and captured images.
6. Build a frontend application that provides interactive light curve visualisation, a target catalogue browser, and data overlay capabilities for comparing space-based and ground-based observations.

7. Validate the system by ingesting real TESS data for known exoplanet host stars and comparing the resulting light curves against published values.

2.4. Scope and Limitations

This project covers the full-stack development of the Nyx platform, from database schema design through API implementation to frontend visualisation. The primary data source is NASA’s TESS mission, accessed via the MAST API. The system is designed to be extensible to other NASA data sources such as the Exoplanet Archive, but integration with additional archives is not a primary deliverable.

The following are explicitly out of scope:

- **Real-time telescope control.** The platform manages observation data after capture, not during acquisition.
- **Automated plate-solving or astrometry.** Users specify their target by name; the system does not attempt to identify targets from image content.
- **Advanced photometric reduction.** The system accepts pre-reduced photometric measurements from ground-based observations. Full aperture photometry from raw images is not implemented.
- **Multi-site deployment.** The system is designed for single-instance deployment. Distributed architecture and horizontal scaling are not addressed.

The default observation site is Mauritius (longitude 57.5°E, latitude 20.3°S), which is used for visibility calculations and observation planning features.

2.5. Report Structure

The remainder of this report is organised as follows. Section 3 reviews existing astronomical data platforms, data pipeline architectures, and relevant technologies, establishing the academic and technical context for the project. Section 4 presents the requirements analysis, including functional and non-functional requirements derived from the problem statement and stakeholder needs. Section 5 describes the system architecture, database schema design, API design, and key design decisions with their rationale. Section 6 details the technical implementation of each major subsystem, including the data ingestion pipeline, authentication system, and frontend application. Section 7 covers the testing strategy, including unit tests, integration tests, and validation against known astronomical data. Section 8 evaluates the project against its objectives, discusses lessons learned, and identifies future work.

3. Literature Review

In this chapter, we review the existing academic and technical context for the tool that we are to develop. Topics covered in this chapter include the sources and formats of astronomical data, the existing platforms and tools in this area, data pipeline architecture, software

architecture, database architecture for time-series data, authentication and security, API design, and the frontend technologies for scientific data visualisation.

3.1. Astronomical Data Sources

3.1.1. The TESS Mission

The Transiting Exoplanet Survey Satellite (TESS) is a NASA Astrophysics Explorer mission that aims to detect exoplanets in most of the sky (Ricker *et al.*, 2015). Unlike its predecessor the Kepler mission that observed a small patch of the sky for four years (Borucki *et al.*, 2010), TESS observes 26 different sectors of the sky, each measuring $24^\circ \times 96^\circ$ in area. Each of the four instruments on the TESS spacecraft can observe $24^\circ \times 96^\circ$ areas of the sky, allowing TESS to survey 2300 square degrees of the sky with its full suite of instruments (Ricker *et al.*, 2015).

The mission produces two main types of data products from these observations. Full-Frame Images (FFIs) and Target Pixel Files (TPFs) and Light Curve Files are collected by the mission and available for researchers. FFIs and TPFs are collected at a cadence of 30 minutes (though reduced to 10 minutes during the extended mission of TESS). The TPFs and Light Curve Files are collected at 2-minute cadence for pre-selected targets by the Science Processing Operations Center (SPOC) at NASA Ames (Jenkins *et al.*, 2016). This Science Processing Operations Center processes the raw data from TESS to produce two different flux measurements for each target TESS observes: the Simple Aperture Photometry (SAP) flux (the flux of the target within an optimal aperture) and the Pre-search Data Conditioning SAP (PDCSAP) flux (an enhanced flux measurement that applies corrections for systematics of the TESS instruments, such as the pointing of the TESS instruments (Stumpe *et al.*, 2012)).

All of the data products from TESS are stored in the FITS file format and made available through the Mikulski Archive for Space Telescopes (MAST). TESS has completed its primary mission (sectors 1-26) and its first extended mission (sectors 27-55). TESS is currently observing during its second extended mission, having observed over 85% of the sky with its survey and discovering more than 7,000 TESS Objects of Interest (TOIs) (Guerrero *et al.*, 2021).

3.1.2. The FITS Data Format

The Flexible Image Transport System (FITS) (Pence *et al.*, 2010) is the data format standard in astronomy, defined by the International Astronomical Union (IAU) FITS Working Group. A FITS file contains one or more Header Data Units (HDUs). Each HDU contains an ASCII header that describes the file contents, and the data itself, which can be in either ASCII or binary format. The primary HDU (designation “primary”) contains the image data or no data at all; additional HDUs are used to contain different data like binary tables.

The light curves of the TESS mission are stored in the binary table extensions of the FITS file. The data contained in these tables include columns such as TIME, SAP_FLUX, PDCSAP_FLUX, PDCSAP_FLUX_ERR, and QUALITY (Tenenbaum and Jenkins, 2018). These tables can be parsed using a FITS library, such as CFITSIO (Pence *et al.*, 2010), or

a general binary file parser that can recognize the FITS file specification. The QUALITY column of these tables is critical to understanding the light curves; any non-zero values in this column indicate measurements of the light curve that should be disregarded in any analysis of the light curve.

The BTJD time system used by the mission is the Barycentric Julian Date minus 2,457,000.0 days. The Barycentric Julian Date is the actual time measurements from the ground observers (in UTC or Julian Date) corrected for the length of time that it takes for light to travel from the object in space to the observer on the ground; this value is at most 8.3 minutes (the light travel time across 1 AU) (Eastman, Siverd and Gaudi, 2010). Thus, while the ground observers use one time standard, the TESS mission uses a different time standard, which can be converted to one another through the use of the geographic and celestial coordinates of the observer and target object.

3.1.3. The MAST Archive

The Mikulski Archive for Space Telescopes (MAST) is the main storage facility for data from space telescopes that observe the universe in the ultraviolet, visible, and near-infrared parts of the electromagnetic spectrum. MAST is hosted by the Space Telescope Science Institute (STScI) in Baltimore (Space Telescope Science Institute, 2024). MAST provides an API to access their stored data. Data can be accessed by making an HTTP POST request to the following URL: <https://mast.stsci.edu/api/v0/invoke>. The API accepts a JSON object with the service that is to be used and the parameters and filters for that service.

The data that is returned by the API is in a “columnar” format; the JSON response includes three separate arrays: one for the names of the columns of the data, one for the type of each of those columns, and one for the values of each row of the data (Space Telescope Science Institute, 2024). The relevant services for accessing TESS data are:

- Mast.Name.Lookup: uses the name of an object in space (such as a star) to return its location in the sky
- Mast.Caom.Filtered.Position: searches for observations of an area of the sky
- Mast.Caom.Products: retrieves the data products from a given sky observation

3.2. Existing Platforms and Tools

3.2.1. Lightkurve

Lightkurve is an open-source Python package for analysing time-series data from the Kepler and TESS missions (Lightkurve Collaboration *et al.*, 2018). Lightkurve provides a high-level API for accessing data directly from MAST, performing operations like light curve flattening, folding and periodogram analysis. The package uses the module to access the archives, and the library for reading FITS files.

While Lightkurve does lower the barrier to analyzing data from the TESS mission for Python developers, it is a library, not a web application. It is dependent upon having a local installation of Python, the use of Jupyter notebooks, and does not have any functionality

for managing observations or comparing them to the available TESS data. Any data is not persisted by the software, and must be downloaded each session.

3.2.2. Exoplanet Transit Database

The Exoplanet Transit Database is a website created and operated by the Czech Astronomical Society that allows amateur astronomers to upload their observations of the transits of exoplanets (Poddany, Brat and Pejcha, 2010). Each observation can be fitted to a model to create a catalogue of Transit Timing Variations (TTVs) for the planets included in the database.

The ETD does not include functions to allow users to view TESS light curves or to ingest data from MAST. Furthermore, the database is focused upon the timing of the transits of the planets rather than providing a means for the comparison of light curves to those of known exoplanets.

3.2.3. AAVSO International Database

The American Association of Variable Star Observers (AAVSO) maintains one of the largest databases of measurements of the brightness of variable stars, receiving over 43 million star brightness measurements from observers around the world (Kafka, 2021). The AAVSO collects data on variable stars and makes it available through various online databases and tools.

The AAVSO performs measurements of the brightness of variable stars over time. It does not perform surveys for exoplanets or provide a way of cross-referencing its observations with those from space-based astronomy missions. It maintains a database of brightness measurements of variable stars, but does not provide visualisation of brightness measurements from space-based observatories.

3.2.4. ExoFOP

The Exoplanet Follow-up Observing Program (ExoFOP) is a web-based platform that is operated by the NASA Exoplanet Science Institute (NExSci) and dedicated to the TESS Objects of Interest (NASA Exoplanet Science Institute, 2019). The website collects observations of these candidates that have been performed by the astronomical community.

ExoFOP is dedicated to the professional astronomical follow-up community. It does not have functionality for light curve visualisation, uploading light curves from amateur astronomers, or managing observations. Thus, it serves a different audience than a platform dedicated to amateur astronomers comparing their light curves to those from TESS.

3.2.5. Gap Analysis

The platform descriptions above cover a subset of the overall problem. Table 1 provides a summary of the capabilities of each of these platforms for five key features of the platform we wish to create.

Platform	TESS Data Access	User Observations	Light Curve Visualisation	Web-Based
Lightkurve	Yes	No	Yes (Python)	No
ETD	No	Yes	Limited	Yes
AAVSO	No	Yes	No	Yes
ExoFOP	Links only	Professional only	No	Yes

Table 1: Comparison of existing platforms across key features.

No existing platform combines direct TESS data ingestion, amateur observation management, and interactive web-based light curve visualisation with data overlay capabilities.

3.3. Data Pipeline Architecture

3.3.1. ETL and ELT Patterns

Data pipelines for ingesting external data typically use either Extract, Transform, Load (ETL) or Extract, Load, Transform (ELT) patterns (Kimball and Ross, 2013). In ETL patterns, data is extracted from the external system, transformed into the target system schema, and then loaded into the target system. In ELT patterns, the data is loaded into the target system in its raw form, and transformed within the target system using SQL or stored procedures.

ETL patterns are typically used when the transformations are complex and best performed with a general-purpose programming language. ELT patterns are typically used when the transformations can be expressed in SQL, and when the data volumes are large enough that loading the data first is efficient (Kimball and Ross, 2013).

Idempotency requires that the same input to a system produce the same output upon repeated invocations. For scientific data systems, idempotency can be achieved by using natural keys from the observation system to create a unique constraint on the data (Kleppmann, 2017).

3.3.2. Batch, Streaming, and On-Demand Processing

Data ingestion can be implemented in three different ways: batch, streaming, and on-demand (Kleppmann, 2017).

Given the infrequent update cycles of the data sources, such as MAST which releases new TESS sectors approximately every 27 days, it is appropriate to use batch or on-demand data ingestion strategies. Streaming data ingestion strategies will add unnecessary infrastructure to the system. An on-demand data ingestion strategy, in which data is imported only when it is requested by a user, represents a compromise between avoiding bulk importing of data that may never be used, and providing fast data access to users through caching (Kleppmann, 2017).

3.3.3. Server-Sent Events for Progress Reporting

Many of the tasks we wish to perform on the server, such as downloading and parsing FITS files, will take several seconds to complete. Server-Sent Events (SSE) is a W3C standard that allows for a server to push data to a client over a single HTTP connection (W3C, 2015). Unlike WebSockets, SSE connections are one-way (from server to client only), utilize standard HTTP protocols, and are automatically supported by the browser's EventSource API. Thus, SSE connections are suitable for situations like reporting the progress of a server task to a client browser.

3.4. Software Architecture

3.4.1. Clean Architecture

Proposed by Martin (2017), the architecture consists of layers of software components whose dependencies must point inward to the inner layers of the software (Martin, 2017). The innermost layer contains the business rules that define the enterprise's business domain, followed by layers that contain application business rules, interface adapters, and finally the frameworks and drivers that implement the software's functionality.

Each of these layers can be tested independently of the rest of the software. For example, the domain and application business rules can be tested using unit tests that mock the dependencies on the interface adapters, database, and other external services. The dependencies of each layer point to abstractions rather than specific implementations of those components and services, which is referred to as the dependency inversion principle (Martin, 2000). In the context of C++, these abstractions are represented as pure virtual classes, with their implementations injected through the constructors of the classes.

3.4.2. Hexagonal Architecture

Hexagonal Architecture, or Ports and Adapters, was proposed by Cockburn (2005) (Cockburn, 2005). Like Clean Architecture, the main idea is to separate the application from the external world. There are two types of ports. Primary ports are driven by the external world, while secondary ports are driven by the application itself.

In the context of the Hexagonal Architecture pattern, the application should be equally testable and playable whether being driven by the user through the web interface, a test harness, or a bash script. Any interaction with the external world should go through these ports, allowing the application to easily substitute any adapter for another.

3.5. Backend Technologies

3.5.1. C++ for Web Services

C++ is not usually used for web applications, where interpreted languages (Python, JavaScript) or garbage-collected compiled languages (Go, Java) are typically used. However, C++ has deterministic memory management that makes it appropriate for applications

that require high performance (Stroustrup, 2013). Furthermore, modern versions of C++ (C++17 and later) include features that improve developer productivity, such as `std::optional`, `std::variant`, `std::expected` (in C++23), structured bindings, and `constexpr` (cppreference.com, 2024).

In addition to the performance characteristics of C++, the language is also used in scientific data processing applications. For instance, C++ is used to implement high-performance scientific libraries that are used in astronomy, such as the CFITSIO library (Pence *et al.*, 2010).

3.5.2. Drogon Web Framework

Drogon is a C++17/20 HTTP application framework (An, 2024). It supports HTTP/1.1 and HTTP/2, WebSocket, and features an ORM to access databases. Drogon employs a multi-threaded event loop architecture similar to Node.js, but using OS threads. Each thread features its own event loop to receive incoming connections. The non-blocking I/O operations, such as database queries or HTTP requests to remote endpoints, are performed asynchronously to improve application performance.

Drogon features a filter system that allows developers to insert code that should execute for every request before it reaches the application’s controllers. Filters are most useful for tasks that apply to all requests, such as authentication, logging, or validating CSRF tokens. Drogon’s controllers are classes whose methods are annotated with macros to map them to HTTP routes. Drogon features an ORM that supports PostgreSQL, MySQL, and SQLite databases with both synchronous and async database access.

3.6. Database Design for Time-Series Data

3.6.1. PostgreSQL for Scientific Data

PostgreSQL is a popular open-source database system that is frequently used in scientific contexts (The PostgreSQL Global Development Group, 2024). Features relevant to astronomical databases include UUID primary keys, `TIMESTAMPTZ`, `DOUBLE PRECISION` fields, partial indexes, and the `ON CONFLICT` clause. For measuring time-series data for objects, the database must be able to efficiently retrieve all data for a given observation. This type of query can be efficiently handled by creating a composite index on the objects’ primary key and the time data fields. Additionally, since astronomical data is often being read and written to simultaneously, PostgreSQL’s MVCC system ensures that reads and writes do not interfere with each other (The PostgreSQL Global Development Group, 2024).

3.6.2. Alternatives Considered

TimescaleDB is a PostgreSQL database extension specifically designed for time-series data, with features like automatic partitioning of tables according to time intervals (hypertables), data retention policies, and time-series optimised aggregation functions (Timescale, Inc., 2024). While these features allow TimescaleDB to handle millions of data points effectively,

the same level of performance is available from standard PostgreSQL for datasets of 10,000 to 50,000 data points per light curve.

InfluxDB does not support storing non-time-series data and would require implementing a polyglot database solution with additional operational overhead (Kleppmann, 2017).

3.7. Authentication and Security

3.7.1. JWT-Based Authentication

JSON Web Tokens (JWT) facilitate stateless authentication by having the server create a token that contains the user's information and has a digital signature that the client includes with each request (Jones, Bradley and Sakimura, 2015). The server can validate this signature without accessing a database to check for login credentials. A JWT consists of three parts: a header, a payload containing claims about the user, and a digital signature.

Because JWTs are stateless, the server has no way of knowing if a token has been issued or is still valid. To combat this, services use a system of two tokens. The short-lived access token is used to authenticate the client with the API and is typically valid for only 15 minutes. The refresh token is valid for a longer period, typically 7 days, and is stored on the server (Jones, Bradley and Sakimura, 2015). With each use of the refresh token, a new one is created and the old one is invalidated. This ensures that if one of the tokens is used to access the API after it has been revoked, all tokens are invalidated (Lodderstedt *et al.*, 2020).

3.7.2. OAuth 2.0

OAuth 2.0 is an authorisation framework that allows third-party applications to gain access to a user's account on another service (Hardt, 2012). The most common flow, the Authorization Code Grant flow, requires four steps to gain access to the user's protected resources. The user visits a frontend application, which redirects the user to an identity provider. Upon authentication by the user, the identity provider redirects back to the client application with an authorization code. The authorization code is sent to the backend application, which redirects back to the identity provider with a request for an access token and an ID token. The backend application decodes the ID token to access user information.

OpenID Connect is built upon OAuth 2.0, and returns a JSON Web Token (JWT) within the ID token. This token contains claims regarding the user that was authenticated. If this token is received directly from the identity provider's servers over HTTPS, it is unnecessary to verify the signature of the token; HTTPS ensures that the token could not have been sent from any other source (Sakimura *et al.*, 2014).

3.7.3. CSRF Protection

If the authentication state is carried within cookies (such as with HttpOnly refresh tokens), then the application is vulnerable to CSRF attacks by a malicious website (OWASP Foundation, 2024a). The double-submit cookie pattern helps to mitigate these attacks by having the server generate a random token to be submitted with requests, which is sent within the

cookie and within the response body to the client's browser. For requests from the client application, the token is sent within a custom request header. The server compares the value of the cookie to the value of the custom header; because the attacker does not have access to the victim's cookie, they will not be able to create a request with the appropriate header (OWASP Foundation, 2024a).

For security, the comparison should utilize constant-time comparison functions to prevent timing attacks that could allow the attacker to gain the value of the token by guessing characters of the token (Bernstein, 2012).

3.7.4. Password Hashing

For securely storing passwords, a memory-hard hashing function must be used. Argon2, the winner of the Password Hashing Competition in 2015, offers three variants: Argon2d is a memory-hard function with data-dependent memory accesses that are resistant to GPU attacks; Argon2i uses data-independent memory accesses that are resistant to side-channel attacks; and Argon2id, a hybrid function of the other two, is recommended for password hashing (Biryukov, Dinu and Khovratovich, 2016). Argon2id with at least 64 MB memory, 3 iterations, and 1 degree of parallelism is the standard recommended by the Open Web Application Security Project (OWASP) for hashing passwords (OWASP Foundation, 2024b).

3.8. API Design

3.8.1. REST Principles

Representational State Transfer (REST) was defined by Fielding (2000) in his doctoral dissertation (Fielding, 2000). The architectural style defines six constraints: separation of concerns between clients and servers, statelessness, cacheability, use of a uniform interface for network protocols, implementation of a layered system architecture, or enabling code-on-demand from server to client. RESTful APIs map different HTTP methods to different operations on the resources defined by the URLs within those requests: GET for retrieving representations of resources, POST for creating resources, PUT or PATCH for updating resources, and DELETE for removing resources from the servers.

Well-designed RESTful APIs use versioning within their routes ((Fielding, 2000)), use plural nouns for the names of the resources they expose, and return responses in a consistent envelope. Errors in those responses should use error codes, error messages, and optionally field-specific validation errors to allow clients to handle those errors appropriately.

3.8.2. Cursor-Based Pagination

For list endpoints that might return large result sets, cursor-based pagination has some advantages over offset-based pagination. Offset-based pagination can suffer from performance issues with larger data sets (Winand, 2012). Each time a request is made for a page of results with an offset, the database must access the data set to find the offset value and then scan forward to the requested page of results. With cursor-based pagination, the cursor value can be used to directly navigate to the page of results via the database index; the

requests will always take the same amount of time, regardless of how deep into the data set the cursor value is.

3.9. Frontend Technologies

3.9.1. Next.js

Next.js is a React-based framework that provides server-side rendering, static site generation, file-system based routing, and API routes (Vercel, 2024). By rendering pages on the server, the content is instantly available for users and can be indexed by search engines.

Next.js 13 introduced a new router called the App Router that uses React Server Components as the default component type. These components are rendered on the server to decrease the amount of JavaScript that needs to be downloaded by the browser and to increase rendering performance on the server. Components that require access to the client side of the application are marked with the “use client” directive.

3.9.2. Data Visualisation

Interactive visualisation of tens of thousands of scientific data points within the browser requires the use of a library like D3.js, the foundational library for data visualisation (Bostock, Ogievetsky and Heer, 2011). However, D3’s use of SVG elements to bind data to visual elements of the visualisation degrades in performance with more than approximately 5,000 data points.

For visualising large time-series data points, Canvas and WebGL are the preferred technology bases for visualisation libraries. Chart.js, a Canvas-based library, and Plotly.js, a library built on D3 but with WebGL support for visualising scatter plots, offer the required performance for interactive visualisation of tens of thousands of data points with zoom, pan, and tooltip interactions (Plotly Technologies Inc., 2024). WebGL can render hundreds of thousands of data points without any performance degradation, meeting the requirements for displaying full TESS light curves.

3.10. Summary

The literature establishes several points about the project. The platform will produce well-documented and publicly available time-series data that adheres to the standard FITS format and can be accessed via the MAST API. Tools available to pull the same type of data require programming knowledge, have limited features, or are geared towards professional astronomers.

The technical literature discusses the use of a clean or hexagonal architecture, PostgreSQL databases, JSON web tokens for authentication, and ETL processes for data ingestion. These technologies will form the technical components of the project that will be discussed in the following chapter.

4. Requirements Analysis

In this chapter, we define the requirements for the Nyx platform. The requirements are derived from the problem statement defined in Section 2 and the gaps in the literature reviewed in Section 3. Furthermore, a stakeholder analysis is performed to determine which individuals will utilise the platform and what their needs are of the platform. The functional requirements are defined within seven subsystems of the Nyx platform. Beyond the functional requirements for the platform, there are also non-functional requirements for the platform. Additionally, the data requirements for the Nyx platform are defined. Use cases for the Nyx platform are also defined. Finally, the requirements are also provided with a MoSCoW analysis and traceability matrices.

4.1. Stakeholder Analysis

The identification of stakeholders is a prerequisite for requirements elicitation. A stakeholder is any individual or group that has an interest in the system, is affected by the system, or that can influence the system (Cockburn, 2005). Nyx serves a niche market of users that includes amateur astronomers from Mauritius, professional astronomers and educators, and the system administrator.

4.1.1. Amateur Astronomers in Mauritius

The audience that will be targeted for Nyx is amateur astronomers based in Mauritius. Mauritius is located in the southern hemisphere at 20.3 degrees south latitude of the equator, which provides observations of objects of the night sky that are inaccessible from most observatories in the northern hemisphere. Furthermore, its longitude of 57.5 degrees east of the prime meridian places it in a geographical location in between most other observatories across the planet (Hessman, 2004). Despite these geographical advantages for astronomy in general, however, there is no existing astronomical infrastructure on the island.

There are several pain points for amateur astronomers in Mauritius in particular. For instance, the available astronomical data from the Transiting Exoplanet Survey Survey (TESS) requires the formation of API requests in JSON format and binary FITS files to access the data for analysis (Space Telescope Science Institute, 2024). Furthermore, there is no available platform for amateurs to upload their observations of targets in the sky. Additionally, the standard time systems for astronomical observations on the ground (Universal Coordinated Time (UTC), or Julian Date) do not match the time system utilized by TESS for its astronomical measurements known as Barycentric TESS Julian Date, which requires a time conversion process for each observation of an object (Eastman, Siverd and Gaudi, 2010). Finally, there is no method for amateur astronomers in Mauritius for recording which astronomical equipment was used to perform each set of observations.

The goals for this audience will be to be able to search for astronomical objects by their common names without needing to be familiar with the various astronomy and sky catalogue identifiers for those objects. Furthermore, they will want to view the TESS light

curves for these objects of interest. Additionally, they will want to be able to upload their observation images to Nyx and automatically have the metadata for those images extracted. Furthermore, they will want to be able to overlay their ground observation measurements onto the TESS light curves of those same objects. Finally, they will want to be able to maintain a record of the equipment used to perform their astronomical observations.

4.1.2. Professional Researchers and Educators

While Nyx is not designed to replace professional research tools such as Lightkurve (Lightkurve Collaboration *et al.*, 2018) or the MAST web portal (Space Telescope Science Institute, 2024), professional astronomers and astronomy educators represent a secondary stakeholder group. Researchers who coordinate follow-up observations of TESS Objects of Interest may use the platform to quickly verify whether an amateur’s observation is consistent with the expected transit signal. Educators may use the platform as a teaching tool, demonstrating how space-based and ground-based photometry differ in cadence, precision, and noise characteristics.

The pain points for this group are different from those of amateurs. Researchers need reliable, well-documented data provenance: they need to know exactly which TESS sector and observation a light curve came from, what quality flags were applied, and whether the flux values represent SAP or PDCSAP measurements. Educators need a platform that is accessible to students without requiring them to install Python environments or learn the MAST API. Both groups require the system to present data accurately, with correct time systems and flux units, and to make clear the provenance of every data point displayed.

4.1.3. System Administrator

The system administrator will be responsible for deploying, configuring, monitoring, and maintaining the Nyx platform. The system administrator desires that the platform is configurable without recompilation, produces logs that can be monitored, and handles errors gracefully.

The pain points for the system administrator relate to the failures of the system. The system should not fail without notice of unavailable dependencies. Any error messages should contain information that can help with troubleshooting, and the system should be able to be deployed on a Linux machine. The system should be able to handle concurrent users without corrupting the data, should have the ability to rate limit access to authentication endpoints to prevent brute force attacks, and should not expose internal error messages to end users.

The goals of the system administrator are to deploy and configure the system, monitor the system logs to ensure everything is operating normally, maintain the security of the system, and ensure that concurrent users will not corrupt the data.

4.1.4. Stakeholder Summary

The three different stakeholder groups, their goals, pain points, and how Nyx addresses each of these pain points has been described in the subsections that precede this section.

The amateur astronomy audience in Mauritius is primarily targeted by Nyx, and Nyx addresses their needs through automation of steps like accessing the MAST API through a search bar, automatically downloading and parsing the resulting FITS files, uploading FITS files and extracting their EXIF data, and providing interactive sky charts. Professional researchers and educators will find value in the software due to the availability of the full TESS observation data in the database, the use of a web interface that does not require installation on the users' computers, and the availability of the SAP and PDCSAP flux measurements of the observed stars. Finally, the system administrator will find the software to be secure through the use of environment variables, spdlog logs with correlation IDs, Argon2id hashing with JWT authentication and rate limiting, and the use of PostgreSQL's MVCC protocol to ensure data access safety.

4.2. Functional Requirements

The functional requirements are organised into seven subsystems. Each requirement has an identifier (FR'X'Y) where X is the subsystem number and Y is the requirement number within that subsystem. Each requirement is described in detail to allow for implementation and testing.

4.2.1. FR1: Authentication and User Management

The authentication subsystem allows users to register for and subsequently log into the application. Because the authentication subsystem is a prerequisite for all other subsystems, only users who have successfully logged into the application can access the features provided by those other subsystems. The authentication system employs the strategy of utilizing both JWT tokens with the refresh token rotation strategy as described in Section 3, as well as requiring users to verify their email addresses when they register for the application.

FR1.1 allows users to register for the application. When a user performs this action, the user is required to provide their email address and password. The system validates that the email address is appropriate for the application (has the correct format and is not already in use) and that the password is of an appropriate complexity before proceeding with registration. If the registration information is valid, a user is registered in the system with their password hashed with Argon2id, an email verification token is generated, and an email is sent to the user with the verification link. The user is not permitted to login until they have verified their email address.

FR1.2 enables users to login to the application. A user provides their email and password upon attempting to login. The application checks to ensure that the user with that email address is validly registered in the system, that their email address has been verified (FR1.5), and that the provided password matches the hashed password associated with their user account. Upon successful login, both a short-lived JWT access token and a refresh token are issued to the user according to the specification described in NFR3. Additionally, any failed attempts to login are logged with the IP address of the user attempting to gain access.

FR1.3 enables users to login to the application using their Google account. The OAuth2 implementation utilizes the Authorization Code Grant Flow as described in (Hardt, 2012). Thus, when a user selects to use their Google account to login to the application, the frontend system redirects the user to Google's authentication screen. Following authentication by the user, Google redirects the user to the frontend with the authorization code. The authorization code is sent to the authentication subsystem's backend server where it is used to obtain an ID token that contains the user's email address and Google ID as described in (Sakimura *et al.*, 2014). If there is no user with that email address in the system, one is created automatically with its email address verified. If there is an existing user with that same email address but who created their account locally, their Google account is linked to that existing user.

FR1.4 enables users to verify their email address. When a user registers for the application, a long-lived, cryptographically random token is generated. The token is hashed with SHA-256, and that hashed value is stored in the system with a expiry date. Additionally, the original, unhashed token is sent to the user through the verification email. When the user clicks on the link included in that verification email, the application hashes the verification token that is provided by the user, compares that hash to the stored hash, and ensures that the verification token has not expired. If all of these parameters are satisfied, the user's account is marked as verified in the system, and their verification token is automatically deleted.

FR1.5 prevents unverified users from logging into the application. When a user attempts to login but whose account is unverified, the login process will reject the user and inform them of the requirements to verify their email address.

FR1.6 allows users to request that a verification email be resent. A user can request the re-sending of a verification email by providing their email address to the system. The system validates that the user exists in the application and that they have not already verified their email address. If these conditions are satisfied, the system automatically invalidates the existing verification token for that user, generates a new one, and sends the user a new verification email.

FR1.7 enables the application to utilize short-lived access tokens and long-lived refresh tokens for users of the application. Additionally, refresh tokens are automatically rotated when they are obtained. When a user presents their valid refresh token to the authentication server to acquire a new access token, the authentication server issues a new access token and refresh token to the user, invalidating the refresh token that is presented to it. Each refresh token is associated with a family of tokens, identified by a family ID. Thus, if a refresh token is found to have been invalidated, all of the tokens within that refresh token's family are automatically invalidated as well (Lodderstedt *et al.*, 2020).

FR1.8 enables users to log out of the application. When a user logs out of the application, the system revokes the user's current refresh token, clears the user's refresh and CSRF tokens in their browser cookies, and returns a success message to the user. While the user will

still be able to use their access token until it naturally expires after 15 minutes, they will no longer be able to use their refresh token to obtain new access tokens after logging out.

As a system, the authentication system is critical to the operation of the application. Without the ability to successfully register for (FR1.1) and login to (FR1.2) the application, no users will be able to use the remaining features of the application. Additionally, the Google OAuth2 login functionality (FR1.3) is an added convenience for users who may be more accustomed to utilizing their Google account than to having to establish a local user account. The requirement for users to verify their e-mail addresses (FR1.4) ensures that the e-mail addresses registered to the application are those of genuine users of the application, which is required for implementing a password reset system in the future. Additionally, the requirement for refresh tokens to be automatically rotated when they are issued (FR1.7) limits the potential damage should a refresh token become compromised (Lodderstedt *et al.*, 2020). Finally, the implementation of a logout function (FR1.8) is both a feature that users will expect to be available, as well as one that is required to complete the authentication lifecycle.

4.2.2. FR2: Target Management

The target management subsystem is responsible for resolving target names, retrieving TESS observation metadata from the MAST archive, discovering FITS data products associated with those observations, and downloading and parsing those FITS files to extract light curve data. This subsystem forms the data processing pipeline for Nyx, distinguishing the platform from existing tools.

FR2.1 Target Name Resolution: Users can search for an astronomical target by its name, such as `texttt{pi Mensae}` or `texttt{HAT-P-7}`. The target name is sent to the MAST API via its `texttt{Mast.Name.Lookup}` service. The service returns a response that includes the name of the astronomical object, its RA and Dec coordinates, and a `texttt{canonical_name}` that can be used to refer to the target in the remainder of the MAST API. These response fields are stored in the database. If the target has been previously looked up by this subsystem, the lookup result is retrieved from the database rather than resolving the target name through the API call to the MAST API.

FR2.2 Coordinate Caching: When an astronomical target is looked up (as in FR2.1), its RA, Dec, and canonical name are stored in the database's `texttt{targets}` table. Any subsequent lookups of that same target will return the target's record from the database, skipping the lookup of its name through the MAST API. The cached coordinates will never time out; since the coordinates of a given astronomical object never change, there is no need for a time-out for the cached record.

FR2.3 TESS Observation Retrieval: Having looked up the astronomical target (FR2.1), the subsystem can query the MAST API for TESS observations of that target. Specifically, the subsystem makes a request to the `texttt{Mast.Caom.Filtered.Position}` service of the MAST API, providing the RA, Dec coordinates of the astronomical target, and the name of the target. The TESS observations are returned as a list of observations that lie within a 0.005 degree radius of the target. Each observation includes the `texttt{obsid}` of the

observation, the `sequence` number of the observation, the `target_name`, the `start_time` and `end_time` of the observation, as well as a `dataURI` that can be used to retrieve the data products related to the observation. These observations are stored in the database in the `tess_observations` table. The `obsid` column of this table is used as the primary key for the table to enable idempotent operations on the observation; downloading the same observation twice will not result in the insertion of the same record twice into the database.

FR2.4 TESS Observation Listing: The subsystem can return a list of observations of the astronomical target that has been looked up. This list will have one observation record for each observation of that target that is stored in the `tess_observations` table. Each observation record will contain the `obsid`, `sequence`, `target_name`, `start_time`, `end_time`, and the `duration` of the observation (duration in seconds), as well as the `lc_points` for that observation. The `lc_points` value will be zero if the light curve for that observation has not yet been downloaded.

FR2.5 FITS Product Discovery: For a particular TESS observation, the subsystem can retrieve the list of FITS data products related to that observation. The list of related products can be obtained by making a request to the `Mast.Caom.Products` service of the MAST API. The response to this request will be a list of products related to the observation. The subsystem parses this list of products to find the FITS light curve file; this file will have a `lc.fits` file extension. The `dataURI` of that FITS file is stored in the `tess_observations` table associated with the observation.

FR2.6 FITS Download and Parse: The FITS file can be downloaded from the MAST archive using the `dataURI` of the file. The file is parsed to extract the light curve data. The FITS file contains a binary table that stores the light curve data. The table has the following columns: the `TIME` of the observation, the `PDCSAP_FLUX`, `SAP_FLUX` of each pixel of the TESS detector, and the `QUALITY` of each flux measurement. The parser of the FITS file uses the `TIME`, `PDCSAP_FLUX`, `SAP_FLUX`, and `QUALITY` columns ((Pence *et al.*, 2010)). The time values are stored as a double-precision floating-point number, the flux values are stored as double-precision floating point number, and the quality value of each pixel is stored as a 32-bit integer. Additionally, TESS light curves may contain `NaN` values for flux measurements; these values are ignored by the FITS parser ((Tenenbaum and Jenkins, 2018)). Furthermore, the FITS file is parsed using raw binary data and pointer arithmetic to access the relevant fields in the file; the CFITSIO library is avoided to minimize the number of external libraries required to compile Nyx.

FR2.7 Light Curve Storage: The light curve points that are parsed from the FITS file are stored in the database. Each record in the table `light_curve_points` contains the `TIME` of the observation as a double-precision floating point number, the `PDCSAP_FLUX`, `SAP_FLUX` values of the pixel in the detector, and the `QUALITY` of that flux measurement. The record also has a foreign key that links the point to the TESS observation from which the point was derived. An index on the `tess_observation_id` and `time` fields of the `light_curve_points` table

enables fast retrieval of the points for a given observation. The points are inserted into the table in bulk to minimize the number of database round trips. Should the subsystem determine that there are already light curve points for that TESS observation in the database, those points are first deleted before the bulk-insertion of the newly parsed points.

The target management subsystem represents the major distinction of Nyx from existing tools for retrieving TESS light curve data. Existing tools require that users either directly access the MAST API, or write Python scripts to retrieve the light curve data from MAST (Lightkurve Collaboration *et al.*, 2018). The target management subsystem of Nyx removes this barrier to accessing the TESS data for amateur astronomers. Furthermore, each step of the data retrieval process can be cached independently. For instance, the coordinates of a target are cached with a permanent time-out (FR2.2), the observations of a target are cached with a time-out related to the ingestion of new targets (FR2.3), and the light curves of the observations are cached with a time-out of the first ingestion of a target's observations (FR2.7).

4.2.3. FR3: Equipment Management

The equipment management subsystem allows the user to maintain a catalogue of their astronomical equipment. This catalogue can then be associated with the observation sessions (FR4) to provide context for the observation regarding the equipment that was used during those observations.

FR3.1 Telescope CRUD: Users can create, read, update and delete telescope objects. Each telescope will have a name that is unique to the user, an aperture in relation to the amount of light that can be gathered by the telescope (in relation to its diameter in millimetres), and the focal length (in relation to the distance of the telescope's mirror or lens to its point of focus and how wide the telescope's field of view is) (Gary, 2007).

FR3.2 Camera CRUD: Users can create, read, update and delete camera objects. Each camera object will have a name that is unique to the user, a sensor type (either CCD or CMOS sensors) that influence the amount of noise in the image that is captured by the sensor (Conti and Conti, 2018), and a resolution of the sensors in megapixels.

FR3.3 Mount CRUD: Users can create, read, update and delete mount objects. Each mount object will have a name that is unique to the user, and the type of mount (equatorial, alt-azimuth, Dobsonian). Equatorial mounts allow for the telescope's field of view to be tracked in relation to the movement of celestial objects in the sky, while alt-azimuth mounts must compensate for field rotation in long-exposure observations. These mounts impact the length of exposure that can be made with the telescope.

FR3.4 Filter CRUD: Users can create, read, update and delete filter objects. Each filter object will have a name that is unique to the user and of a given type (Johnson V, Johnson B, Sloan g', luminance, no filter). Using different filters allows for ground-based telescopes to observe in different wavelength bands of the electromagnetic spectrum. For instance, the TESS telescope captures all light within a broad red portion of the spectrum (between 600 and 1000 nm in wavelength) (Ricker *et al.*, 2015).

While the equipment management subsystem is somewhat simpler than the others, it is still essential to provide context for the observations. Without knowing the type of equipment used by an astronomer to perform their observations, it is impossible to understand why their observations may differ from those made by the TESS telescope. Furthermore, the equipment type has a unique constraint upon the (user_id, name) of each type of equipment to avoid adding entries for the same object under different user IDs or different names within the same user's database.

4.2.4. FR4: Observation Management

The observation management subsystem allows ground-based observation sessions to be recorded (with associated equipment and location records), and for the images from those observations to be uploaded and processed.

FR4.1 Observing Location CRUD: Users can create, read, update, and delete observing location records. Each location record has a name (which is required to be unique to each user), latitude in decimal degrees, longitude in decimal degrees, and altitude in metres above sea level. These geographic coordinates are required for time system conversions to convert between, for instance, UTC/JD (used in ground-based observation) and BJD (used in TESS data), (Eastman, Siverd and Gaudi, 2010). All users in Mauritius are assigned a default observing location: latitude -20.3, longitude 57.5.

FR4.2 Observation Session Creation: Users can create observation sessions that record the details of a single observation session for a specific astronomical target. Each observation session record is associated with the astronomical target that was observed (via link to the target record from FR2.1), the location from which the observations were made (via link to the location record from FR4.1), and the observing equipment that was used (via link to equipment items from FR3.1-FR3.4). Each observation session record also includes a start time for the session and additional notes about the observations made during that session. Those observation sessions are the link between observation images and the astronomical targets that those images were of.

FR4.3 Image Upload: Users can upload observation images to an observation session. Supported file types are JPEG, PNG, FITS and DNG (Digital Negative) files. Uploaded files are stored on the server and their filename is set to a generated value. The observation session record in the database is updated with the file path to the uploaded file, the original filename of the file, the size of the file in bytes, and the MIME type of the file. Each observation session can contain multiple observation images.

FR4.4 EXIF Metadata Extraction: When a JPEG or PNG image is uploaded to an observation session (as defined in FR4.3), the system will automatically extract the EXIF data from the image file. Such metadata includes the manufacturer and model of the camera that captured the image, the length of time that the image was exposed to light (in seconds), the sensitivity of the camera's sensor to light (ISO), the date and time that the image was taken, the focal length of the camera lens that took the image, and the geographic coordinates of the location from which the image was taken (if the image contains that information). This extracted metadata is stored in a JSON field within the observation session's record in

the `observation_images` table. By automatically extracting this information, observations can be recorded without requiring users to manually enter these parameters for each observation.

The observation management subsystem is the counterpart to the target management subsystem; while subsystem FR2 handled data from space-based telescopes like TESS, subsystem FR4 handles data from ground-based observations from the user's own telescope. More specifically, the linking of observation sessions to astronomical targets (as described in FR4.2) is what enables the implementation of the comparison visualisation described in FR5.3; without establishing these links between observation and target records, the software would not be able to associate any ground-based observations with the targets from TESS. Furthermore, the implementation of automatic extraction of exposure parameters (as described in FR4.4) is beneficial because it allows the system to automatically record those parameters at the time the observation was made (rather than requiring the users to manually enter those values after the fact).

4.2.5. FR5: Data Visualisation

The data visualisation subsystem provides the frontend components that are required for displaying the data that has been stored in the backend. The subsystem transforms the raw data from the backend into visual representations that allow the user to analyse the data.

FR5.1 requires the frontend to display the light curve data in the form of interactive scatter plots. Time is represented on the horizontal axis of the chart, and flux is represented on the vertical axis. Each point on the plot represents a data point from the TESS mission. The plot should display PDCSAP flux measurements as the default setting, but allow users to select the display of SAP flux measurements. The frontend must be capable of displaying up to 50,000 data points before any lag is introduced to the display of the plot. Implementing SVG graphics libraries will not meet this requirement, and Canvas or WebGL based graphics libraries should be used instead (Plotly Technologies Inc., 2024).

FR5.2 requires the light curve charts to allow the users to zoom into specific portions of the light curve for closer viewing. Zooming into specific portions of the light curve can be performed using the scroll wheel on a mouse or touch gestures on a touch device. Panning the light curve to view different portions of the plot can be performed by clicking and dragging on the plot. The axis labels and tick marks will adjust to the portion of the plot that is zoomed in on. Additionally, there should be a button on the plot that resets the display to the entire light curve. Such interactions are essential for being able to examine specific features of a full-length TESS light curve that can take up to 27 days to complete and contain tens of thousands of data points (Ricker *et al.*, 2015).

FR5.3 requires the frontend to allow for the overlay of the ground-based observation data on the TESS light curve. The ground-based data displays with a different colour and marker shapes to indicate that they are not TESS observations. By displaying both datasets on the screen simultaneously, the user can compare their ground-based observations of the same object to the observations made by TESS. The ground-based data will be displayed in

terms of relative flux only, as the flux measurements from these two data sources are not normalised to the same scale.

FR5.4 requires the frontend to provide a searchable catalogue of the astronomical objects that have been resolved in the system. The catalogue will display the name of the object, the type of object, its coordinates in the sky, and the number of TESS observations of that target. The user will be able to search for objects by name, and any row can be sorted by any of the displayed fields. Clicking on an object will navigate the user to a page containing details about the object, a list of its TESS observations, and the light curves of those objects.

As the primary means of deriving value from the Nyx platform, the data visualisation subsystem is essential to the platform's value proposition. The value proposition of the Nyx platform is to provide access to TESS data to amateur astronomers, and to allow those amateur astronomers to compare such measurements to their own ground-based observations of those same objects (FR5.1, FR5.2, and FR5.3). Without the data visualisation subsystem, the backend and ingestion subsystems (FR2) and the observation management subsystem (FR4) will have produced data that cannot be accessed or utilised by the user. The requirement for 50,000 data points to be displayed (FR5.1) can be derived from the typical length of a TESS light curve. A full sector of TESS has a 2-minute cadence and observes for 27 days. During that time, TESS performs approximately 19,400 observations per sector. It is possible for an object of interest to be observed in multiple sectors during these 27 days. Thus, 50,000 data points is the rounded up value of the observations per 27 days (Ricker *et al.*, 2015).

4.2.6. FR6: Data Pipeline

The subsystem that manages the execution of the ingestion tasks must manage tasks that may take several seconds to complete. While the resolution of targets (FR2.1) and observation search (FR2.3) tasks may be completed in sub-second time, the tasks of performing product discovery on TESS observations (FR2.5) and downloading and parsing light curves (FR2.6) can take several seconds due to the nature of downloading data from the MAST archive. The execution subsystem for the application allows for these tasks to be executed while reporting to the user about their status.

FR6.1 Asynchronous Ingestion: Tasks that take several seconds to complete (such as discovering light curves and parsing them from their FITS files) will execute in the background of the web application. When a user begins ingestion of data from a TESS observation, the system will return an HTTP response indicating the ingestion has begun, but will execute the task in a background thread to allow for ingestion to begin without time-outs on the HTTP requests (An, 2024).

FR6.2 SSE Progress Reporting: The system will report the status of an ingestion task to the user through Server-Sent Events (SSE) (W3C, 2015). Each event will describe the stage of the ingestion task (such as discovering products, downloading the FITS file, parsing the light curve, storing the data points) and whether the task is completed. The frontend of the system will use the EventSource API to subscribe to these events (W3C, 2015). Using Server-Sent Events instead of WebSockets is driven by the requirement that the communication

is unidirectional (from the server to the client only); additionally, using standard HTTP is beneficial due to the ease of proxy and firewall configurations (W3C, 2015).

FR6.3 Idempotent Re-Ingestion: Attempting to ingest the same target or observation will not result in the creation of two separate records of the same information. Records of TESS observations include a unique constraint on the MAST obsid. Additionally, when re-ingesting observations, the system uses the ON CONFLICT DO NOTHING statement to exclude any data that may already exist (The PostgreSQL Global Development Group, 2024). For individual points of light curves, if the system re-ingests an observation, the existing points will be first deleted, then the system will re-insert the newly-parsed light curve data. Idempotency ensures that re-running the ingestion task (whether as a result of an intentional re-run or due to system failures during ingestion) will not result in data corruption of the database (Kleppmann, 2017).

The pipeline task execution subsystem helps to address the difficulty of implementing a web application that calls external APIs that may take several seconds to complete the requested tasks. Without asynchronously executing the tasks (FR6.1), it would be impossible to complete the HTTP requests and receive a response from the web server. Additionally, without reporting the status of ingestion tasks to the frontend (FR6.2), the user would be unaware of the status of the system's tasks. Finally, without ensuring that re-running the ingestion tasks will not lead to data corruption (FR6.3), the database could become corrupted or otherwise contain data that is no longer accurate or reliable.

4.2.7. FR7: Image Processing and Photometry

The image processing subsystem is responsible for performing photometry on ground-based observation images. While the TESS data is pre-processed such that it is published as flux measurements within FITS files, the ground-based observations must have flux measurements extracted from the raw images via aperture photometry. Thus, this subsystem performs the necessary functions to transform raw observation images (FR4.3) into flux measurements (FR5.3) that can be compared with TESS data.

FR7.1 EXIF Metadata Extraction: The system can extract EXIF metadata from the JPEG and PNG observation images that are uploaded to the database. Such metadata includes information about the observation device (camera make and model), the exposure settings (aperture, shutter speed, ISO), the date and time stamp of the observation, the focal length of the device was used, and GPS coordinates of the observation location (where available). This information is stored in the database as a JSON object associated with the observation image record. This extraction occurs automatically upon the upload of the observation images (FR4.4).

FR7.2 DNG Raw Image Decoding: Raw images in the DNG (Digital Negative) format can be decoded on the system. DNG files are raw files that are used by astrophotographers to store direct data from the camera sensor in uncompressed format, which allows for greater dynamic range during image processing (Conti and Conti, 2018). The raw data is decoded into a pixel array for use by the system. Raw observation images are required to be decoded prior to performing aperture photometry on those raw observation images (FR7.3).

FR7.3 Aperture Photometry with Source Detection: Aperture photometry can be performed on the decoded observation images. The system first determines the approximate location of the target star within the observation image. The system then detects the exact center of the observation source within the image, and determines the centroid of that source within the image (Conti and Conti, 2018). Using this detected center, the system creates an aperture of a selected radius around that detected source, creates an annulus outside that aperture to measure background flux, determines the total flux within the aperture, subtracts the background flux, and reports the resulting flux measurement of the detected source. The source detection algorithm can determine the centroid of the source to sub-pixel precision for accurate aperture placement (Conti and Conti, 2018).

FR7.4 Flux Measurement with Error Estimation: The flux measurement can also be accompanied by an estimate of the error in that measurement. For example, the error can be determined through calculations of the uncertainty in the photon count of the target star (Poisson statistics), background noise (from the background annulus pixel values), and the noise in the readout of the camera sensor (Gary, 2007; Ricker *et al.*, 2015). This error estimate is stored together with the flux measurement, which can then be utilized by the visualisation subsystem (FR5.3) to visually represent the measurement errors of the ground-based observations.

The image processing subsystem represents the most technically demanding subsystem within the ground-based observation system. Without the ability to perform photometry on those images (FR7.3), the raw observation images are merely pictures of the stars of interest. Furthermore, the measurement errors within FR7.4 are particularly important for ground-based observations. Ground-based observation images tend to contain a higher level of noise than the measurements provided by TESS. For instance, amateur astronomers using ground-based telescopes typically achieve only 1-5% precision in their photometry measurements of stars, while TESS achieves sub-millimagnitude precision measurements for the same stars (Gary, 2007; Ricker *et al.*, 2015). Thus, without error measurements for ground-based observations, amateur astronomers may incorrectly believe that their ground-based observations reflect genuine signals from those stars being observed.

4.3. Non-Functional Requirements

Non-functional requirements define the quality attributes that the system should exhibit. Unlike functional requirements, which define what the system will do, non-functional requirements define in what way the system should perform those functions. The non-functional requirements for Nyx include requirements relating to performance, security, reliability, maintainability, and operational concerns of the system.

NFR1: API Response Time - API calls to data that is cached will return within 200 milliseconds. API calls that require additional calls to external APIs (like MAST) will not be included in these response time requirements. Such a response time is required because 200ms is the threshold at which human users can begin to notice delays in a system's responsiveness.

NFR2: Password Hashing - All passwords will be hashed using Argon2id, with at least 64 MB of RAM allocated to hashing that password, 3 iterations of hashing, and with 1 degree of parallelism (OWASP Foundation, 2024b). This choice of hashing algorithm ensures that attackers can not perform brute force attacks on the system; with 64 MB of RAM allocated to hashing the password, an attacker with 64 GB of RAM can only perform around 1,000 password hash attempts at once, whereas unsalted SHA-256 can perform billions of password hash attempts per second (Biryukov, Dinu and Khovratovich, 2016). Argon2id was chosen because it resists both GPU attacks (using Argon2d) and side channel attacks (using Argon2i).

NFR3: Token Expiry - Access tokens will expire after 15 minutes, and refresh tokens will expire after 7 days. Access tokens will be included in the API response's JSON response body, which is stored in the client-side application in memory (rather than in localStorage to avoid being accessed by XSS attacks). Refresh tokens will be stored as an HttpOnly, Secure, SameSite=Strict cookie restricted to the /api/v1/auth API endpoint (Jones, Bradley and Sakimura, 2015). This strategy ensures that access tokens have a short lifespan (limiting damage if stolen), while allowing for convenience in the user experience (only refreshing after 7 days of inactivity).

NFR4: CSRF Protection - All endpoints that permit a user to make changes to the system will utilize the use of a CSRF double-submit cookie (OWASP Foundation, 2024a). When a user logs into the system, a random token will be generated by the backend. That token will be returned in both the cookie and the response body. The response body will be stored by the client-side application in memory. Any requests sent by the client will include this same token in an X-CSRF-Token request header. Any requests that do not include the correct token will be denied with a 403 Forbidden response code.

NFR5: Rate Limiting - Requests made to authentication endpoints will be limited to a maximum of 10 requests per minute per IP address. This limits potential threats to authentication endpoints, such as brute-force password attacks on users, and DoS attacks against the computationally-intensive Argon2id password hashing algorithm. Rate limiting is enforced on the backend in memory. Any requests that reach the rate limit will be denied with a 429 Too Many Requests response code.

NFR6: Consistent Response Envelope - All API responses will be in the same structure. Successful responses will include a data field with the content of the response and a meta field with information about the request. Error responses will have a response in the data field replaced by an error field that includes information about the error. This enables error handling on the client-side, and monitoring of API endpoint calls by automated monitoring tools (Fielding, 2000).

NFR7: Error Information Hiding - Any internal errors of the server will not be made visible to the client applications. Internal error messages will not include details about the system's internal structure (database queries, system tables, files, etc.). This prevents attackers from gaining knowledge of potential vulnerabilities of the system (OWASP Foundation, 2024a).

NFR8: Correlation ID Tracing - Every request to the backend server will have a unique correlation ID associated with it, which will be logged each time the request is processed by the server. This allows backend services to correlate incoming requests with server logs, which is helpful with identifying and fixing issues with those requests. This functionality is especially important for Nyx because of the need to trace requests to asynchronous services like MAST.

NFR9: Concurrent Access Safety - The system will be able to handle multiple users at the same time. Database access is performed by PostgreSQL using its MVCC model to ensure that multiple processes reading and writing to the same database tables will not interfere with each other's processes (The PostgreSQL Global Development Group, 2024). Both write and read processes are handled by the Drogon web framework, which is able to handle high levels of concurrent requests made to the server (An, 2024). The Nyx application is stateless, except for its use of the database to store user information.

NFR10: Platform Compatibility - The backend APIs will be compiled and run on Linux using GCC 13+ or Clang 17+. Its dependencies are managed using CMake and vcpkg, both of which do not use proprietary libraries. The client application will be able to run in any web browser that supports ES2020 and the EventSource API (Vercel, 2024). This ensures that the backend server can be deployed on Linux servers, and accessed from any device using a modern browser.

NFR11: RAII Resource Management for FITS Files - All resources for FITS files will use RAII (Resource Acquisition Is Initialisation) to ensure that allocated resources (RAM) are released when the object using those resources goes out of scope (Stroustrup, 2013). FITS files downloaded from MAST will be stored in a container of type `std::vector`, whose memory is automatically released when the container goes out of scope. This prevents memory leaks, especially since FITS files can be tens of megabytes in size. RAII also ensures that the allocated memory is released when multiple FITS files are downloaded in a sequence.

NFR12: Batch Size Tuning for Bulk Inserts - Bulk inserts of data (light curve points) to the database will occur in batches rather than all at once. Using parameterised SQL statements, bulk insertions will be limited to a configurable batch size. The default batch size ensures that insertion times remain within a few seconds (rather than tens of seconds) for light curves with up to 18,000 points (Winand, 2012).

The non-functional requirements for Nyx are just as important as the functional requirements for the system. An API that takes several seconds to respond to requests will provide an unpleasant user experience; a system that does not appropriately secure user passwords is a liability to the organisation that deploys the system; a system that returns internal error codes in its API responses can present a security risk; a system that does not properly manage memory may crash under sustained use; and the non-functional requirements define the quality of the system that is ultimately required for Nyx to be a successful platform.

4.4. Data Requirements

The data to be handled by the Nyx platform is described in this section. An understanding of the data that will be stored is a prerequisite to the database schema design (Section 5) as well as to making effective decisions regarding indexing and storage of the data.

4.4.1. TESS Light Curve Data

The TESS light curve files are distributed in the form of FITS binary table files. Each file corresponds to a single target that was observed in a single sector of TESS (approximately 27.4 days of observation). The file contains multiple Header Data Units (HDUs). HDU 2 of the file contains the actual data (Pence *et al.*, 2010).

The relevant columns in the table files are:

TIME: The time column contains values of Barycentric TESS Julian Date (BTJD). BTJD is defined as the Barycentric Julian Date minus 2,457,000.0 days (Eastman, Siverd and Gaudi, 2010). This value is stored as a 64-bit floating point number with FITS format code D. Typical values for this column range from 1325 to 1353. Any cadence with no flux measurement will have a NaN value for this column.

PDCSAP_FLUX: This column contains values of the Pre-search Data Conditioning Simple Aperture Photometry. This flux measurement is corrected by the SPOC pipeline for instrumental systematics (Stumpe *et al.*, 2012). This value is stored as a 32-bit floating point number with FITS format code E. Typical values for this column range from a few hundred to several million electrons per second.

SAP_FLUX: This column is similar to the PDCSAP_FLUX measurement except that the flux is not corrected for systematics. This value is stored in the same format as the PDCSAP_FLUX measurement. By comparing the values of these two measurements, the systematics of the TESS camera can be determined.

QUALITY: This 32-bit integer value contains information on potential issues with that specific data point (Tenenbaum and Jenkins, 2018). For instance, bit 0 indicates that there was an attitude tweak to TESS' pointing during that observation, bit 1 indicates a safe mode, bit 3 indicates a cosmic ray within the optimal aperture, and so on. A quality of 0 indicates that there were no known issues with the observation. Any non-zero quality values indicate that the data point should be treated with caution.

A typical TESS light curve file contains between 18,000 and 20,000 rows of data (27.4 days of observation / day / 720 cadences per day). However, since NaN values are present in the flux columns for some observations, there are typically between 15,000 and 19,000 rows of usable data. For stars that are observed in multiple sectors of TESS, the total amount of data can reach several hundred thousand rows.

4.4.2. MAST API Response Format

The MAST API returns data in a columnar JSON format, which is different from the row-oriented JSON format that is typical of REST APIs (Space Telescope Science Institute, 2024).

The response to a request to the API contains two arrays: an array of objects that describe the fields of the data (their names and types) and an array of rows. Each row is an array whose elements correspond to the values in each of the fields of the data for that row of the result table. For instance, if the lookup of a name returns information about the object, the fields array will contain fields describing values like `ra`, `dec`, `obj_type`, and `canonical_name`, and the data array will contain the resolved object data in the rows of that array.

The columnar structure of the response is efficient during data transmission, as the field names are only transmitted once with each row of data rather than being repeated with each row. However, row-oriented data structures are required by most databases for insertion into those databases. Additionally, the response to each request from the API also includes metadata regarding the request, such as the number of results of the query, the status of the query, and any error messages that were returned in the case that the query failed. These responses from the API must be parsed by the software, any errors handled, and the data transformed into objects of the application domain.

4.4.3. Ground-Based Observation Data

Data from ground-based telescopes enters the system as image files in one of four different file formats:

- JPEG files are compressed with EXIF data but are unsuitable for photometry due to image compression.
- PNG files are lossless compressed but do not contain EXIF data.
- FITS files are the standard file format in astronomy but are uncommon among amateur astronomers. However, they are the standard among amateur astronomers who take serious astrophotography.
- DNG files are raw files from Adobe cameras that contain raw sensor data. These files are increasing in use among amateur astrophotographers with astronomy cameras and even smartphone cameras.

For ground-based observations, the following metadata must be collected: time stamp (UTC), exposure time, ISO setting, and the name of the target object. The following metadata would also be helpful but not necessary: make and model of the camera, focal length, GPS coordinates, and temperature of the surroundings of the telescope.

4.4.4. Photometry Data

When aperture photometry is performed on the ground-based observation image (FR7.3), the following measurements are made on each source within the image:

- Raw flux: The sum of the pixel values of the source within the aperture, after subtracting the background flux; this value is in arbitrary units (ADU) or in units of electrons if the gain of the telescope was set to multiply the raw pixel counts by a factor to convert them to units of electron counts.

- **Flux error:** The uncertainty in the raw flux value of the source; this is calculated from the quadrature sum of the photon noise of the source, the background noise, and the read noise of the detector.
- **Relative flux:** The flux of the target star divided by the flux of a comparison star; this value cancels out the effects of atmospheric extinction. This quantity is most comparable to the TESS PDCSAP flux of the star.
- **Aperture parameters:** The radius of the aperture, the radius of the inner annulus, and the radius of the outer annulus; these are all measured in pixels. These values have to be reported with the flux measurements to other astronomers in order to permit for the measurements to be made with the same apertures.

4.4.5. Data Volume and Access Pattern Summary

The following summarises the data types, their formats, typical volumes, and the primary access patterns that must be supported efficiently.

Target metadata. Format: JSON from MAST. Typical volume: hundreds of bytes per target. Storage: PostgreSQL targets table. Primary access pattern: lookup by name; lookup by ID.

TESS observation metadata. Format: JSON from MAST. Typical volume: approximately 500 bytes per observation, with 1–20 observations per target. Storage: PostgreSQL tess_observations table. Primary access pattern: list by target ID; lookup by obsid.

TESS light curve points. Format: binary FITS. Typical volume: approximately 18,000 points per observation; 4 doubles plus 1 int per point (approximately 36 bytes); approximately 650 KB per observation. Storage: PostgreSQL light_curve_points table. Primary access pattern: range scan by observation ID, ordered by time.

Observation images. Format: JPEG/PNG/DNG/FITS. Typical volume: 1–50 MB per image; 1–100 images per session. Storage: filesystem. Primary access pattern: list by session ID; individual image retrieval.

EXIF metadata. Format: JSON. Typical volume: approximately 1 KB per image. Storage: PostgreSQL JSON column in observation_images. Primary access pattern: read with parent image record.

Photometry results. Format: numeric. Typical volume: approximately 100 bytes per measurement; 1–10 measurements per image. Storage: PostgreSQL columns in observation_images. Primary access pattern: read with parent image record; aggregate by session.

Equipment metadata. Format: JSON. Typical volume: approximately 200 bytes per item; 1–20 items per user per type. Storage: PostgreSQL equipment tables. Primary access pattern: list by user ID; lookup by ID.

User accounts. Format: structured. Typical volume: approximately 500 bytes per user. Storage: PostgreSQL users table. Primary access pattern: lookup by email; lookup by ID; lookup by Google ID.

Next is the Tess light curve points. Each TESS observation contains approximately 18,000 data points. If an object is observed in 10 different sectors of the sky, there will be approximately 180,000 data points for that object’s light curve. Thus, with 1,000 different targets and 5 observations of each target, the light curve points table will contain approximately 90 million rows. While this is within the capabilities of PostgreSQL, creating the appropriate index on the table will be necessary to ensure that each query returns the desired rows within the 200ms target of NFR1 (Winand, 2012).

4.5. Use Cases

The following section describes each of the use cases for the Nyx platform in detail. Each use case diagram includes a description of the actors for the system, the preconditions for accessing the described use case, the main flow of the use case, any alternative flows for non-standard scenarios, exception flows for errors in the system, and the postconditions for the use case. Each of these descriptions are written in the fully-dressed format recommended by Cockburn (Cockburn, 2005).

Figure 1 illustrates the primary use cases for the two actor types: unauthenticated visitors and authenticated users.

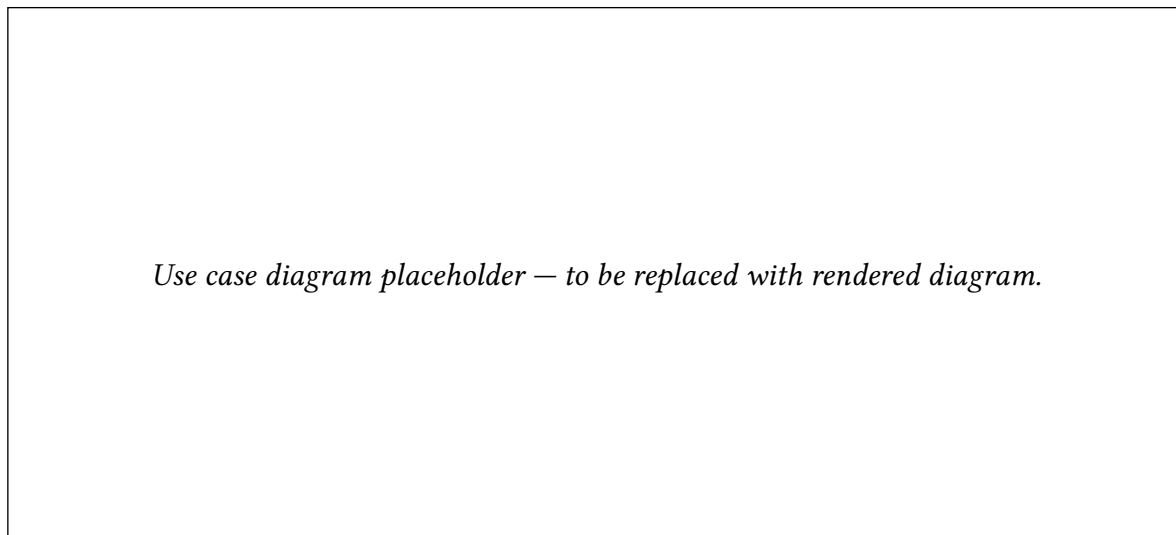

Figure 1: Use case diagram showing interactions for unauthenticated and authenticated users.

The system has two types of actors. Unauthenticated actors can perform registration (UC1) and login using Google OAuth (UC7). Authenticated actors can search for and resolve astronomical targets of interest (UC2), fetch light curves of those targets (UC3), perform ground-based astronomical observations of those targets (UC4), perform aperture photometry on astronomical targets of interest (UC5), and compare space- and ground-

based observations of those targets (UC6). All of these use cases except for UC1 and UC7 require the user to be authenticated.

4.5.1. UC1: Register and Verify Email

The registration use case covers the full lifecycle from account creation through email verification to first login. This is the primary onboarding path for users who do not use Google OAuth.

Actors: Unauthenticated visitor, email system.

Preconditions: The visitor has access to the Nyx frontend and a valid email address.

Main Flow:

- The visitor visits the Nyx website and clicks the registration button.
- On the registration page, the visitor enters their email and a password that meets the minimum complexity requirements.
- The frontend sends a registration request to the `/api/v1/auth/register` endpoint.
- The backend validates the entered email and password. Both validations pass.
- The backend checks whether there is an existing account with the provided email. No existing account is found.
- The backend securely hashes the visitor's password using Argon2id encryption.
- The backend creates a new user account in the database with the hashed password and sets their email verification status to false.
- The backend generates a verification token for the account, hashes the token with SHA-256, and saves the hashed token in the database.
- The backend sends a verification email to the visitor with a link that includes the original verification token.
- The backend responds to the registration request with a 201 Created status code.
- The visitor receives the verification email and clicks on the link with the verification token.
- The frontend extracts the verification token from the URL and sends a request to the `/api/v1/auth/verify-email` endpoint.
- The backend verifies the validity of the verification token by hashing it and looking it up in the database.
- The backend marks the visitor's account as verified in the database and removes the verification token record.
- The backend responds to the request with a 200 OK status code.
- The visitor can now log in to the Nyx website with their account.

Alternative Flow A – Email Already Registered:

At step 5, if the provided email address is already taken, the API will return a 409 Conflict response with an error code of `EMAIL_ALREADY_EXISTS`. The visitor will be informed that their email is already registered with the system and will be redirected to the login or password reset page.

Alternative Flow B – Verification Token Expired:

If the verification token has expired (more than 24 hours since token generation), a 400 Bad Request response will be returned with the error code of TOKEN_EXPIRED. The user will be required to request a new verification email via the resend verification endpoint (FR1.6).

Alternative Flow C – Resend Verification Email:

If the visitor does not receive the verification email or the token expires, the visitor will be redirected to the resend verification page where they will have to enter their email address once more to initiate the sending of a new token that invalidates the previous one.

Exception Flow – Email Service Unavailable:

If the email sending service is unavailable at step 9, the backend server will log the error using the correlation ID to investigate the root of the problem, create the user account, and return a 201 Created response with a warning message that the verification email was not sent and the user must request a resend of the email. The account will remain in the unverified state.

Postconditions: A new user account exists in the database. If the verification succeeds, the account will be marked as verified and the user will be able to log in. However, if the verification has not yet occurred, the account will exist in the database, but login will be blocked until the user verifies their email address.

Related functional requirements: FR1.1, FR1.4, FR1.5, FR1.6.

4.5.2. UC2: Search and Resolve Target

This use case describes the interaction between the user and the application when the user wishes to search for an object by name.

Actors: Authenticated user.

Preconditions: The user is logged in with a valid access token. The MAST API is accessible from the backend server.

Main Flow:

- The user navigates to the target search page on the frontend.
- The user enters the name of the astronomical target to be searched for (e.g., pi Mensae).
- The frontend's JavaScript code sends a POST request to the /api/v1/targets/resolve endpoint, with the name of the target to be searched for in the request's request body, and with the user's access token and CSRF token included in the request's headers.
- The JwtAuthFilter receives the request and validates the user's access token.
- The CsrfFilter receives the request and validates the CSRF token.
- The TargetController receives the request and calls the resolve_target() method of the TargetService.

- The TargetService checks whether there is a record in the targets table with the target's name. There is no record with that name in the table.
- The TargetService calls the resolve_target() method of the MastClient implementation of the IMastClient interface.
- The MastClient implementation of the IMastClient interface sends a POST request to the MAST server at the URL <https://mast.stsci.edu/api/v0/invoke>, with the service field set to Mast.Name.Lookup and the target name field set to the name of the target to be looked up.
- The MAST server returns the canonical name, right ascension, declination, and object type of the astronomical target in JSON data in a columnar format (i.e., a format in which the data is returned as comma-separated key-value pairs).
- The MastClient implementation of the IMastClient interface parses the returned JSON data, converting it from a columnar format to a structured object in memory.
- The TargetService inserts the astronomical target into the targets table, and returns the target data to the TargetController.
- The TargetService calls the search_tess_timeseries() method of the IMastClient interface, providing the right ascension and declination of the target, as well as a search radius of 0.005 degrees of the target.
- The MastClient implementation of the IMastClient interface sends a POST request to the MAST server at the URL <https://mast.stsci.edu/api/v0/invoke>, with the service field set to Mast.Caom.Filtered.Position, the ra field set to the right ascension of the target, the dec field set to the declination of the target, and the level field set to 3.
- The MAST server returns a list of observations that meet the criteria of the request (i.e., that occurred at the location of the target, and that are TESS timeseries observations at calibration level 3).
- The TargetService saves the list of observations to the tess_observations table, using the ON CONFLICT clause to ensure that it only inserts the observations if there is no record of them already in the table.
- The TargetController returns a 200 OK response to the frontend.
- The frontend displays the results of the search to the user.

Alternative Flow A — Target Already Cached:

At step 6, if the service finds a cached record in the targets table, it skips steps 7-10 to resolve the MAST name and returns the target with its observations. This provides sub-200ms response time for previously resolved targets.

Alternative Flow B — No TESS Observations Found:

At step 14, if the MAST server does not return any TESS observations for the target, then the target is still cached in the database (it may have other observations from other missions, or it may be observed during future sectors by TESS). The response from the server indicates that there are no TESS observations available for that target.

Alternative Flow C — Target Name Not Recognised:

At step 9, if the result of the query to MAST is an empty result set, the service will return an error to the controller. The controller will return a 404 response code with the error code of TARGET_NOT_FOUND and a message asking the user to check the spelling of the target name or to attempt to use an alternative name for that object.

Exception Flow — MAST API Unavailable:

If the MAST API is unreachable or returns a non-200 status code during any of the steps that involve a MAST API call, the service will log the error message with the correlation id and the MAST API response, and return an error response to the calling system. The controller will return a 502 Bad Gateway response to the client indicating that the external data source is unavailable temporarily.

Postconditions: The target is stored in the database with its celestial coordinates. Any available TESS observations are stored in the `tess_observations` table linked to the target.

Related functional requirements: FR2.1, FR2.2, FR2.3, FR2.4.

4.5.3. UC3: Fetch Light Curve

This use case describes the process of retrieving and downloading a TESS light curve for a specific observation. This includes the steps of discovering the FITS products for an observation, downloading the binary file containing the light curve data, parsing the FITS file, and performing a bulk insert of the TESS light curve data into the database.

Actors: Authenticated user.

Preconditions: User is authenticated. Target has been resolved (UC2) and there is at least one observation in TESS for this target. MAST API is accessible.

Main Flow:

- The user sees the list of observations for the resolved target (from UC2).
- The user chooses an observation, triggering a fetch of its light curve.
- The frontend sends a POST request to the back-end server to the following endpoint: `/api/v1/targets/observations/{id}/light-curve`.
- The backend validates the user's authentication and CSRF tokens.
- The TargetController calls the TargetService::fetch_light_curve() method.
- The method first checks whether there are any light curve points already associated with the observation. If so, those points are deleted.
- The method calls the IMastClient::get_data_products() method of the IMastClient implementation, passing in the observation's obsid.
- The MastClient implementation sends a POST request to MAST with the service field set to `Mast.Caom.Products`.
- MAST returns the list of data products for that observation, including the type of each product, the name of the file, the size of the file, and the data URI for the file.
- The method filters the list of data products to find the light curve file (whose filename ends in `_lc.fits`). The product is found.

- The method calls the `IMastClient::download_fits()` method, providing the data URI of the found light curve file.
- The `MastClient` implementation sends an HTTP GET request to the light curve file on MAST's server: `https://mast.stsci.edu/api/v0.1/Download/file?uri=`. The implementation receives the file content as a byte vector.
- The service calls the `IFitsParser::parse_light_curve()` function of the `IFitsParser` implementation, providing the byte vector of the light curve file's data.
- The `FitsParser` implementation examines the headers of the file to locate the binary table data (HDU 2). The method inspects the `TFIELDS`, `TTYPE`, and `TFORM` fields of each of the columns to determine the size and endianness of each field's data.
- The method reads the data of the `TIME`, `PDCSAP_FLUX`, `SAP_FLUX`, and `QUALITY` fields into a vector of `LightCurvePoint` structs. The `PDCSAP_FLUX` field is filtered to remove any points with NaN flux values.
- The method calls the repository pattern: the service calls the newly created `ILightCurvePointRepository::save_batch()` method, passing in the vector of points to be saved.
- The repository creates an SQL INSERT statement that includes all of the point data in a parameterised form and executes the statement against the database.
- The method returns the number of points to the target service.
- The target service returns a 200 OK response to the client that requested the points.
- The frontend displays a success message to the user, and offers to navigate to the light curve viewer.

Alternative Flow A – Light Curve Already Fetched:

At step 6, if there are existing points in the light curve, they will be deleted before being re-ingested into the database. This ensures that if the light curve is re-fetched, the result will be the same as if it had just been fetched for the first time. Thus, it is not necessary to warn the user of the deletion of the existing data, since the data to be inserted is of the same source as the existing data and will be of equal or improved quality.

Alternative Flow B – No Light Curve Product Found:

At step 10, if no data product with a filename ending in `_lc.fits` is found, the service will return an error. The controller will return a 404 response code with the error code `LIGHT_CURVE_NOT_FOUND`. This error can occur for observations that only contain FFI data or for observations for which the SPOC pipeline has not yet generated the light curve file.

Exception Flow – FITS Parse Failure:

At step 14, if the FITS file is malformed or does not contain the expected columns, an error is returned by the parser. The error is logged by the service using the correlation ID and the obsid of the observation. The controller will return a 500 internal server error (with a generic message to the client as defined by NFR7) while logging the error message in the server logs.

Postconditions: The table `light_curve_points` contains the time series data for this observation. The data is ready for visualisation via FR5.1.

Related functional requirements: FR2.5, FR2.6, FR2.7, FR6.1, FR6.3.

4.5.4. UC4: Record Ground-Based Observation

This use case describes the process of creating an observation session, associating equipment and location, and uploading observation images with metadata extraction.

Actors: Authenticated user.

Preconditions: The user has been authenticated. The user has created at least one observing location (FR4.1), and possibly has equipment records (FR3.1–FR3.4). The user has resolved a target (UC2).

Main Flow:

- The user navigates to the Observation Management page.
- The user clicks on the “New Observation Session” button and fills out the form with the following fields: selects a target to observe from the list of resolved targets, selects an observing location, and optionally adds information about the telescope, camera, mount, and filter that will be used for observation.
- The form data is sent to the backend through a POST request to the `/api/v1/observation-sessions` endpoint.
- The backend validates that the observation session parameters are valid (for instance, that the target, location, and equipment belong to the currently logged in user). If all parameters are valid, the backend creates the observation session in the `observation_sessions` database table.
- The backend responds to the user with a 201 Created response that contains the id and details of the newly-created observation session.
- The user navigates to the detail page for the newly created observation session.
- Within the session detail page, the user clicks on the “Upload Image” button.
- The user selects one or more image files of type JPEG, PNG, DNG, or FITS from their local machine.
- The files are uploaded to the server through a multipart POST request to the `/api/v1/observation-sessions/{id}/images` endpoint.
- The backend validates that the uploaded files are of a valid type and size. Valid files are stored on the server’s filesystem with a unique filename.
- For JPEG files, the backend extracts metadata regarding the image that was taken (such as the camera model, exposure time, ISO, the date and time when the image was taken, the focal length of the lens that was used to take the image, and the geographical coordinates of the location of the image’s subject (if visible in the image)).
- A record is created in the `observation_images` table for the newly uploaded image, with fields for the file path on the server, the original filename, the type of file (MIME type), the size of the file, and the extracted image metadata (stored as a JSON object in the database).

- The backend responds to the user's request with a 201 Created response that contains the details about the newly-inserted image record (including the extracted image metadata).
- The observation session detail page displays the uploaded image along with its extracted image metadata.

Alternative Flow A — No Equipment Selected:

If the user does not select any equipment items during step 2, the session that is created will have null foreign keys for the fields related to the equipment. The inclusion of equipment for a session is not required for the session to be created, as the user might not yet own that equipment, or might be observing a session that does not include any equipment use.

Alternative Flow B — PNG Without EXIF:

Step 11: If the uploaded file is a PNG, there will be no results from the EXIF data extraction (PNG files do not have a standardized EXIF container). PNG files store the image with null metadata. The observation parameters can be manually entered by the user in this case.

Exception Flow — File Too Large:

At step 10, if the size of the uploaded file exceeds the maximum allowed size, the request is rejected by the server with a 413 Payload Too Large response. The maximum file size is specified via an environment variable and has a default value of 50 MB.

Postconditions: There is an observation session in the database with the target, location, and equipment information. The images from those observations are on the filesystem with metadata in the database. The ground-based data from these observations can be compared with the TESS light curves (UC6).

4.5.5. UC5: Run Aperture Photometry

This use case describes the process of extracting a flux measurement from an observation image. The raw image can be transformed into a flux measurement that is comparable to TESS measurements.

Actors: Authenticated user.

Preconditions: The user is authenticated. An observation session exists with at least one uploaded image (UC4). The image is in a suitable format for photometry (DNG or FITS file formats; JPEG images have non-linear pixel values that make them unsuitable for photometry).

Main Flow:

- The user navigates to the observation page and selects the uploaded image.
- The image is displayed to the user, who can click on the target star to select it.
- Upon clicking the target star, the frontend records its (x, y) pixel coordinates.

- The frontend presents the user with the aperture parameters to configure. These include the aperture radius, the inner annulus radius, and the outer annulus radius. The values suggest default settings for the aperture.
- The frontend sends a POST request to the photometry API endpoint along with the image ID, the target star's coordinates, and the aperture settings.
- The backend loads the image using the image loader. If the image is of type DNG, the DNG decoder (FR7.2) extracts the raw pixels from the file. If the image is of type FITS, the FITS parser extracts the image from the first HDU of the file.
- The photometry algorithm detects the centre of the source within the image close to the clicked star. This is performed by calculating the intensity-weighted mean within a search box around the target star.
- The algorithm sums the flux from the pixels within the aperture centred on the detected source.
- The algorithm calculates the background level as the median of the pixels within the annulus between the inner and outer annulus radii.
- The background contribution to the flux is subtracted from the summed flux to determine the net flux from the target.
- The flux error is calculated as the quadrature sum of three components: the square root of the summed flux (photon noise), the standard deviation of the pixels within the aperture (background noise), and the read noise of the camera's sensor (if available).
- The backend stores the photometry results (flux, flux error, aperture settings, and centroid) into the `observation_images` record in the database.
- The API controller returns a 200 OK response to the frontend with the photometry results.
- The frontend displays the photometry results (along with an image overlay to indicate the aperture and annulus) to the user.

Alternative Flow A – Centroid Failure:

If the centroiding algorithm cannot converge to a valid position (for instance, if no astronomical source is found close to the coordinates that the user has clicked upon), then the backend will return an error message to the client application. The user will be prompted to click on the target star again, or to change the size of the search box.

Alternative Flow B – JPEG Image Warning:

At step 6, if the image is a JPEG, the backend will perform the photometry but will also return a warning that the measurements may not be reliable due to the non-linear nature of the pixel values that are applied during JPEG compression. This warning will be returned in the response metadata for the user to consider when deciding how to use the measurements.

Postconditions: The observation image record is updated with the measured flux, flux error, aperture parameters, and centroid position. The flux measurement can be used to overlay on TESS light curves (UC6).

4.5.6. UC6: Compare Space-Based and Ground-Based Data

UC6 describes how the user wishes to view the TESS light curve and the recorded ground-based observation on an interactive chart. Use case 6 depends upon the completion of UC3 (TESS light curve fetched) and UC4/UC5 (ground-based observation recorded and measured).

Actors: Authenticated user.

Preconditions: The user has been authenticated. The target has been resolved with at least one observation from TESS whose light curve has been fetched (UC3). The user has at least one observation session for the same target with photometry measurements (UC5).

Main Flow:

- User navigates to the detail page for a target that has both TESS and ground-based data
- User selects the TESS observation to display
- Frontend requests the light curve data for the selected observation from the `/api/v1/targets/observations/{id}/light-curve` endpoint and plots the data as a scatter plot with the x-axis representing the BTJD and the y-axis representing the PDCSAP flux
- User toggles the switch to show ground-based data on top of the light curve
- Frontend sends a request to the backend to retrieve the user's observation sessions for the target
- For each observation session, the frontend retrieves the timestamps of the observations (converted from UTC to Barycentric Julian Date) and plots each session's photometric measurements
- The flux of the TESS data is scaled to 1 by dividing by the median out-of-transit flux measurements. The relative flux measurements of the ground-based observations are also scaled to 1 (to their baseline). The relative flux is represented as a value between 0 and 1.
- Each of the user's ground-based observations are plotted onto the TESS light curve with a different colour and marker style. Error bars are plotted for each observation if the ground-based flux error is known for that observation.
- User can zoom into the region of the light curve that represents the user's observation session
- User can toggle between the TESS PDCSAP and SAP flux values
- User can hover over data points to see tooltips with relevant information about that data point

Alternative Flow A – No Ground-Based Data:

If the user does not have any observation sessions or photometric measurements for this target, the toggle to display the overlay will be disabled. The user can still view the TESS light curve without the overlay.

Alternative Flow B – Time Mismatch:

If the timestamps from the ground-based observations do not overlap with the TESS observation time range (e.g., the ground-based observations were taken during a different TESS

sector or between TESS sectors), then the overlay will be displayed, but the data points will be plotted at different positions along the x-axis. In this case, the user will be made aware that these observations were taken at different times.

Postconditions: No data is modified. The use case is only a read and a visualisation process.

4.5.7. UC7: Google OAuth Login

This use case describes the authentication flow to be followed by users who want to log in to the application using their Google account.

Actors: Unauthenticated visitor, Google OAuth provider.

Preconditions: The visitor has a Google account. Backend is configured with valid Google OAuth2 client credentials. Google's authentication servers are accessible.

Main Flow:

- The visitor navigates to the application and clicks on the "Sign in with Google" button.
- The frontend application is configured to redirect the visitor to Google's OAuth2 screen with the application's client ID, redirect URI and scopes (Hardt, 2012).
- The visitor authenticates on Google and grants the requested permissions to the application.
- Google redirects the visitor back to the Nyx application with an authorisation code included in the URL.
- The frontend application exchanges the authorisation code for authentication and refresh tokens by sending a request to Nyx's `/api/v1/auth/google` API endpoint.
- Nyx's authentication API endpoint sends a request to Google's token endpoint with the client ID, client secret, authorisation code and redirect URI.
- Google returns an ID token, an access token and a refresh token.
- Nyx decodes the ID token to extract the user's email address and name. Because the ID token was issued by Google's servers over the HTTPS protocol, the authenticity of the token is guaranteed by the transport layer (Sakimura *et al.*, 2014).
- Nyx checks whether an account with the user's email address already exists in the database.
- If no account exists with that email address, Nyx creates a new user account with a user ID that is set to the subject of the Google's ID token, the user's email address with the "verified" attribute set to true (as Google has verified the user's email address), and sets the application's authentication provider attribute to "google".
- If an account exists with that user's email address but whose authentication provider is of type "local", Nyx sets the account's user ID to the subject of Google's ID token, and sets the account's authentication provider attribute to "google". The user can now login with either authentication provider.
- If an account with the user's email address and authentication provider attribute of "google" already exists, Nyx does not need to make any changes to the account.

- Nyx generates an access token and a refresh token for the authenticated user following the same strategy as local authentication (FR1.7).
- Nyx returns the access and CSRF tokens in the response message, and sets the refresh token as an HttpOnly cookie.
- The user is now authenticated and can access any end points that are protected by authentication.

Alternative Flow A – User Denies Consent:

At step 3, if the visitor denies the permission request on the consent screen of Google, the Google server will redirect the visitor with an error parameter. The frontend will display the message: Google login was cancelled.

Alternative Flow B – Invalid Authorisation Code:

At step 6, if the authorisation code is invalid or expired, Google's token endpoint returns an error and the backend returns a 401 Unauthorized.

Postconditions: The user is authenticated with a valid access token and refresh token. If this was the first Google login, a new user account exists in the database linked to the Google subject ID.

Related functional requirements: FR1.3, FR1.7.

4.6. MoSCoW Prioritisation

MoSCoW prioritisation groups requirements into four categories: those that are a Must Have (the omission of which would mean that there is no minimum product), those that are a Should Have (important requirements that can be worked around), those that are a Could Have (desirable features) and those that are a Won't Have (requirements that will be excluded from the current development iteration but may be included in future iterations). This prioritisation of requirements helps to determine the development iteration in which they will be met.

4.6.1. Must Have

The Must Have requirements form the minimum viable product for the platform. Without these requirements, the platform will not be able to fulfill its purpose of allowing users to ingest and interact with the TESS data.

- FR1.1 (User registration): Users cannot access the system without an account.
- FR1.2 (User login): Authentication is required for all data operations.
- FR1.4 (Email verification): Prevents the creation of spam accounts; only users with reachable email addresses can join the system.
- FR1.5 (Unverified user restriction): Enforces the email verification policy.
- FR1.7 (Token rotation): A security mechanism for logging in and out of the application.
- FR1.8 (Logout): Users expect the ability to log out of the application.
- FR2.1 (Target name resolution): A function that allows users to access data from TESS.

- FR2.2 (Coordinate caching): Avoids calling the MAST API; lookup times are under 200ms.
- FR2.3 (TESS observation retrieval): Retrieves information about TESS observations of a target star.
- FR2.4 (TESS observation listing): A method that allows users to view the observations of a target star.
- FR2.5 (FITS product discovery): Finds the light curve of the target star in FITS format.
- FR2.6 (FITS download and parse): Downloads and parses the light curve of a target star in FITS format.
- FR2.7 (Light curve storage): Stores the light curve for ease of access.
- FR3.1 to FR3.4 (Equipment CRUD): Equipment information is required to associate observations with a piece of equipment.
- FR4.1 (Observing location CRUD): Location information is required for time zone conversions.
- FR4.2 (Observation session creation): Used by organisations to create an observation session.
- NFR1 (API response time < 200ms): A quick response time is required to enhance the user experience.
- NFR2 (Argon2id password hashing): Argon2id passwords are required to meet security standards (OWASP Foundation, 2024b).
- NFR3 (Token expiry): Limits the time during which a user is logged in.
- NFR6 (Consistent response envelope): Frontend applications require a consistent response envelope to appropriately handle errors.
- NFR7 (Error information hiding): Errors exposed to the users should not expose information to potential attackers.
- NFR8 (Correlation ID tracing): Required for debugging issues with the system, especially since the system makes external API calls.
- NFR9 (Concurrent access safety): System should be able to handle multiple users of the application.
- NFR10 (Linux compatibility): The application will be deployed onto a Linux server.

4.6.2. Should Have

The Should Have requirements for a project are important, but not necessary. These requirements should be developed after the Must Have requirements are implemented.

- FR1.3 (Google OAuth2 login): Reduces registration friction, important for adoption but local login suffices.
- FR1.6 (Resend verification email): Handles edge cases well but not needed.
- FR4.3 (Image upload): Needed for ground-based telescope data but not needed for TESS data.
- FR4.4 (EXIF metadata extraction): Automates metadata capture from images but not needed as users can manually add metadata.
- FR5.1 (Interactive light curve charts): Main visualisation of data, hence needed.
- FR5.2 (Zoom and pan): Essential for light curve exploration but static chart is a fallback.
- FR5.4 (Target catalogue): Enhances navigation but users can search for targets.

- FR6.1 (Asynchronous ingestion): Prevents timeouts when processing large amounts of data but synchronous processing is fine for smaller datasets.
- FR6.2 (SSE progress reporting): Enhances user experience during long operations but polling for progress is a fallback.
- FR6.3 (Idempotent re-ingestion): Important for correctness but can be ignored during early stages of development.
- NFR4 (CSRF protection): Important security measure in addition to OAuth2 authentication.
- NFR5 (Rate limiting): Helps protect against brute-force attacks but less important for a single-user application.
- NFR11 (RAII for FITS files): Prevents memory leaks when files are no longer needed but less important than other features.
- NFR12 (Batch size tuning): Optimises the application for fast ingestion of data but the default setting works correctly albeit slowly.

4.6.3. Could Have

Requirements that could help add significant value to the platform are included in the Could Have section. These features are beyond the scope of the must have and should have requirements but may be implemented if time permits after the fulfillment of those requirements.

- FR5.3: Describes the value proposition, which is based on the assumption that photometry is functional.
- FR7.1: Adds support for photometry, though this is not essential for the system's operation.
- FR7.2: Allows for photometry of raw images, in addition to the alternative input of FITS images.
- FR7.3: Performs aperture photometry on the input images; this will require some implementation effort.
- FR7.4: Estimates the error in the photometry measurements; this feature will add scientific rigour to the application, but can be added incrementally.

4.6.4. Won't Have (This Iteration)

The following requirements are not being met in this iteration of the project. Though these requirements will be valuable features for the software product, implementing these features will exceed the scope of this project.

- Real-time telescope control is outside the scope of this project. Although protocols like ASCOM and INDI exist for communicating with telescope hardware, their integration would be outside the scope of this project.
- Automated plate solving uses large reference catalogues of stars and algorithms to determine which part of the sky an exposure shows. Since users input the name of their target of observation, solving for the plate is outside the scope of this project.

- A differential photometry pipeline is a project in itself. The application includes a simple aperture photometry package that calculates the brightness of objects in observations. A full photometry pipeline could be implemented in future versions of this project.
- An observation planner that calculates the visibility of celestial objects from a given location on the Earth is a valuable feature for planning observations. This feature is implemented in the frontend only and does not relate to the data processing pipeline.
- While features like sharing observations with other users or viewing community galleries of observations is beneficial to the concept of astronomy as a social science, these features are outside of the scope of this project because they are not needed for the single-user observation workflow.
- This project is specifically designed to run as a single instance. Distributed systems concepts such as load balancing or container orchestration are outside the scope of this project. The database uses features like MVCC that allow it to handle concurrent user sessions. Drogon, the web framework used to implement the backend API, is also multi-threaded which allows it to handle multiple requests from users simultaneously.

The MoSCoW categorisation reflects the project’s priorities as a data engineering dissertation. The Must Have requirements focus on the data pipeline (target resolution, observation retrieval, FITS parsing, light curve storage) and the security baseline (authentication, password hashing, error handling). The Should Have requirements extend the pipeline with asynchronous execution and progress reporting, add the frontend visualisation, and implement additional security measures. The Could Have requirements address the ground-based photometry workflow, which is the most technically demanding aspect of the platform but is dependent on the core pipeline being functional first. The Won’t Have requirements are documented to set clear expectations about the project’s boundaries.

4.7. Requirements Traceability

Requirements traceability ensures that each objective of the project is both satisfied by at least one requirement, and that each requirement is contributing to at least one of the project’s objectives. This section provides two traceability views: one mapping project objectives (from Section 2) to functional requirements, and one mapping functional requirements to the non-functional requirements that constrain their implementation.

4.7.1. Objectives to Functional Requirements

The following map each project objective to the functional requirements that implement it. The objectives are numbered as they appear in the Aim and Objectives section of Section 2.

- Objective 1: Develop the C++ backend (REST API, background jobs, SSE) - FR1.1-FR1.8, FR2.1-FR2.7, FR3.1-FR3.4, FR4.1-FR4.4, FR6.1-FR6.3.
- Objective 2: Build the data ingestion pipeline (MAST API, TESS, FITS) - FR2.1, FR2.2, FR2.3, FR2.5, FR2.6, FR2.7, FR6.1, FR6.3.
- Objective 3: Implement PostgreSQL persistence layer - FR2.2, FR2.3, FR2.7, FR3.1-FR3.4, FR4.1, FR4.2.

- Objective 4: Develop user authentication - FR1.1, FR1.2, FR1.3, FR1.4, FR1.5, FR1.6, FR1.7, FR1.8.
- Objective 5: Implement observation management functionality - FR3.1-FR3.4, FR4.1-FR4.4, FR7.1-FR7.4.
- Objective 6: Build the React frontend - FR5.1, FR5.2, FR5.3, FR5.4.
- Objective 7: Validate system with real TESS data - FR2.6, FR2.7, FR5.1, FR5.3.

Each objective has at least two functional requirements associated with it. Objective 1 (REST API backend) has the most requirements mapped to it overall, as it forms the basis of the other components of the system. Objective 2 (data ingestion pipeline) is linked to the target management and data ingestion pipeline requirements. Finally, objective 7 (validation) is associated with the FITS parsing and visualisation requirements, as the validation component requires both the ability to ingest real data and display it.

4.7.2. Functional Requirements to Non-Functional Requirements

The following maps the functional requirements to the non-functional requirements that constrain and quality gate the implementation of the functional requirements. This mapping ensures that implementers understand which non-functional requirements apply to each functional requirement.

- FR1.1 (Registration): NFR2 (Argon2id hashing), NFR5 (rate limiting), NFR6 (response envelope), NFR7 (error hiding), NFR8 (correlation ID).
- FR1.2 (Login): NFR2 (password verification), NFR3 (token expiry), NFR4 (CSRF token issued), NFR5 (rate limiting), NFR6, NFR7, NFR8.
- FR1.3 (Google OAuth): NFR3 (token expiry), NFR4 (CSRF token issued), NFR6, NFR7, NFR8.
- FR1.7 (Token rotation): NFR3 (token expiry enforcement), NFR4 (CSRF rotation), NFR9 (concurrent refresh safety).
- FR2.1 to FR2.3 (Target resolution, observation retrieval): NFR1 (200ms for cached targets), NFR6, NFR7, NFR8, NFR9 (ON CONFLICT for concurrent resolution).
- FR2.5 to FR2.7 (FITS discovery, download, parse, store): NFR1 (200ms for stored light curves), NFR6, NFR7, NFR8, NFR11 (RAII for FITS data), NFR12 (batch insert tuning).
- FR3.1 to FR3.4 (Equipment CRUD): NFR1 (200ms response), NFR4 (CSRF on mutations), NFR6, NFR7, NFR8, NFR9.
- FR4.1 to FR4.4 (Observation management): NFR1, NFR4, NFR6, NFR7, NFR8, NFR9.
- FR5.1 to FR5.4 (Visualisation): NFR1 (200ms for data retrieval), NFR10 (browser compatibility).
- FR6.1 to FR6.3 (Pipeline): NFR8 (correlation ID across async boundaries), NFR9 (idempotent writes), NFR11, NFR12.
- FR7.1 to FR7.4 (Image processing): NFR6, NFR7, NFR8, NFR11 (RAII for image buffers).

The traceability mappings reveal several patterns. First, NFR6, NFR7, and NFR8 are satisfied by every functional requirement - these are implemented in the middleware. Second, NFR9 is satisfied by functional requirements involving concurrent writes to the same resources, such as when two users attempt to resolve the same target, or when a user modifies

equipment while viewing it in another tab in the application, or when attempting to ingest the same pipeline twice in succession. Finally, NFR11 is satisfied only by the requirements related to FITS files and image processing - both of these involve large amounts of binary data to be processed.

4.7.3. Summary

Having performed each of the steps described in this chapter, the Nyx platform has requirements that have been established through the analysis of stakeholders, functional requirements, non-functional requirements, data requirements, use cases, and the MoSCoW and traceability matrices. The following chapter will translate these requirements into a system design for the Nyx platform.

5. System Design

This chapter presents the complete system design of Nyx. Nyx's backend system architecture is described in this chapter, as are the database schema and indexing strategy, the REST API, the TESS data ingestion system, the system for parsing FITS files, the system for processing and performing photometry on ground-based images, the time system converters, the authentication and authorisation system, the HTTP middleware system, the frontend system architecture, and the trade-offs that were made in the design of each of these systems.

5.1. System Architecture

The backend follows an architecture established by Martin (Martin, 2017), consisting of four main layers. Each layer has a specific responsibility and only has dependencies upon layers within it; outer layers may depend upon inner layers, but no inner layer has a dependency upon an outer layer. This structure is a means of applying the Dependency Inversion Principle (Martin, 2000) to the software packages. This strategy provides three main benefits to the system. First, the domain and application layers are entirely free of framework-specific code; they can be tested with mock objects instead of the framework's production objects. Second, any changes to the infrastructure layer require only changes to that specific layer; the other layers are not affected by such changes. Third, the firewall that is established by the interface between the infrastructure and application layers reduces compilation times; changes to the infrastructure do not affect the compilation time of the application layer objects.

Figure 2 illustrates the four layers and their dependency directions.

Architecture diagram — concentric layers: Domain (innermost) → Application → Infrastructure → Presentation (outermost). Arrows show dependency direction inward.

Figure 2: Clean architecture layers of the Nyx backend. Dependencies point strictly inward.

5.1.1. Domain Layer

The domain layer is the innermost ring. It contains two categories of artefact: entity structs and repository interfaces.

The entity structs are plain C++ aggregates with no behaviour beyond what the language provides for aggregate types. The entities defined in this layer are:

- Target: an astronomical object with a name, coordinates, and type (Star, Exoplanet Host)
- TessObservation: an observation sector from TESS with an observation id (obsid), cadence in seconds, start and end times for the observation (in MJD), and a URI to its light curve file
- LightCurvePoint: a point in a light curve with a timestamp (in BTJDT), PDCSAP and SAP flux data (optional), PDCSAP flux error (optional), and a quality flag
- User: an account with an email address, password (optional), display name, authentication provider, Google ID (optional), and a verification status
- RefreshToken: a token with a SHA-256 hash, a family id, a revocation status, and an expiry date
- VerificationToken: a token used to verify a user's email with a SHA-256 hash, an expiry date, and a used timestamp (optional)
- ObservationSession: an observation of an astronomical object by a user using a given piece of equipment
- ObservationImage: an image taken during an observation of an astronomical object with information about the image file (path, size, type), image metadata (EXIF data) including date/time taken, camera model, aperture, shutter speed, ISO, GPS coordinates, image dimensions, and photometry results (target pixel coordinates, raw flux, relative flux, status)
- Telescope, Camera, Mount, Filter: equipment owned by a user, specific attributes to each type of equipment

- **ObservingLocation**: a location from which astronomical observations are made with a latitude, longitude, and Bortle class
- **Repository** interfaces define the data access contracts that the application layer relies on. Each interface is a pure abstract class with a virtual destructor and one or more pure virtual methods. For example, `ITargetRepository` declares methods `create`, `find_by_id`, `find_by_canonical_name`, and `find_all`. `ITessObservationRepository` declares `bulk_create`, `find_by_target_id`, `find_by_id`, `find_existing_obsids`, and `update_data_uri`. `ILightCurvePointRepository` declares `bulk_create`, `find_by_observation_id`, `find_by_observation_id_as_json`, `count_by_observation_id`, and `delete_by_observation_id`. There are 13 repository interfaces in total, one for each aggregate root or entity that requires persistence.

The domain layer has zero dependencies on external libraries. It only uses the C++ standard library (`std::string`, `std::optional`, `std::vector`, `std::expected`). This makes it the most stable layer in the system - it will only ever change when the model of the data that we are representing changes.

5.1.2. Application Layer

The application layer is situated immediately outside of the domain layer. This layer contains service classes that implement the use cases for the system. Each service class in this layer is responsible for fulfilling one use case. The following services are defined in this application layer:

- **TargetService** — resolves target names from the MAST API, finds TESS observations of that target, finds FITS data products of that target, downloads and parses light curves from that target, and retrieves stored light curve data from the database. This service is the most complex of all the services, and implements the four-stage data ingestion pipeline described in Section 5.5.
- **AuthService** — enables user registration, login via email and password or Google OAuth2, logout, refresh tokens (along with rotation for security), login with verified email addresses, and resending verification emails to users.
- **EquipmentService** — enables creation, retrieval, update, and deletion (CRUD) of telescope, camera, mount, and filter objects for the currently logged in user.
- **LocationService** — enables creation, retrieval, update, and deletion (CRUD) of location objects for the currently logged in user.
- **ObservationService** — enables creation of observation objects and upload of the images taken during that observation. Images are automatically downloaded in raw DNG format, EXIF data is extracted from those raw images, and light curve data is generated via aperture photometry of the raw images.
- **ProfileService** — enables users to complete their profiles after registration via OAuth2.
- **LightCurveComparisonService** — retrieves the TESS light curve data for a target with the user's own light curve data for that same target, converting the user's observation times to the TESS time system for direct comparison between the two light curves.

All the services depend on interfaces, not on the implementations of those interfaces. For instance, the `TargetService` depends on interfaces such as `IMastClient`, `IFitsParser`, `ITargetRepository`, `TessObservationRepository`, `LightCurvePointRepository`, and `IUuidGenerator`. Each of these is an abstract class. The concrete implementations of these classes are provided by the application at startup time through constructor injection.

The application layer also defines Data Transfer Objects (DTOs), which are the structs that represent both the requests that are made to (and received by) the API endpoint (such as `ResolveTargetRequest`, `RegisterRequest`, and `LoginRequest`), and the responses that are returned (such as `TargetResponse`, `TessObservationResponse`, and `LightCurveResponse`). For instance, a `TargetResponse` object includes a vector of `TessObservationResponse` objects that are not a part of the domain model represented by a `Target` entity.

5.1.3. Infrastructure Layer

The infrastructure layer contains the concrete implementations of the interfaces declared in the domain and application layers. This layer has the widest ring of external dependencies, thus having the most potential for change. The implementations are as follows:

- **Persistence:** There are thirteen repository implementations, one for each interface. Each uses the Drogon ORM to interact with the PostgreSQL database; parameterized queries are used exclusively, and bulk inserts are supported for tables with up to 5,000 rows.
- **NASA API client:** The `MastClient` class implements the `IMastClient` interface and uses Drogon's HTTP client to communicate with the NASA MAST Portal API. Form-encoded POST requests are used to call the MAST API; the request body is encoded and placed into the request form field with content type `application/x-www-form-urlencoded`.
- **FITS parsing:** The `FitsParser` class uses the CFITSIO library to read the `TIME`, `PDCSAP_FLUX`, `PDCSAP_FLUX_ERR`, `SAP_FLUX`, and `QUALITY` columns from the binary FITS files. The library does not support reading from in-memory buffers, so the file is written to a temporary file on disk and read in memory.
- **Security:** The `JwtTokenService` class uses the `jwt-cpp` library to create and validate JWT tokens; Argon2id passwords are hashed using libsodium with the `MODERATE` security parameter.
- **Authentication:** The `GoogleAuthClient` class uses the Google OAuth2 API to authenticate users via the authorization code grant to obtain the access token from Google's authorization endpoint.
- **Email:** Both the `SmtplibEmailSender` and the `ConsoleEmailSender` class implement the `IEmailSender` interface; the `ConsoleEmailSender` is used during development only.
- **Imaging:** The `Exiv2ExifParser` class uses the `Exiv2` library to read EXIF metadata from images; the `LibrawDngDecoder` class uses the `LibRaw` library to decode raw DNG images; the `AperturePhotometer` class performs aperture photometry on images.
- **Configuration:** The `EnvironmentConfig` class obtains all configuration from environment variables; there are no configuration files used by the application.
- **Storage:** The `LocalFileStorage` class stores files on the local filesystem.

5.1.4. Presentation Layer

The presentation layer is the outermost ring of the system. It receives and processes HTTP requests, and returns HTTP responses from the system. It is divided into two sub-layers: controllers and middleware.

Controllers are classes that inherit from Drogon's `HttpController` class. Each method of a controller does three things: it parses the request body and path parameters, calls a method on the application service class, and returns a response in JSON format. The response is constructed using a class called `ResponseHelper`. If the service method call encounters an error, the error is passed directly to the `ResponseHelper::error()` method, which turns the service's `ErrorCode` into an HTTP response code and JSON error object.

The `ResponseHelper` class is used to construct both successful and error responses. A successful response includes the following structure in the response body: `{"data": ..., "meta": {"request_id": "...", "timestamp": "..."} }`. An error response includes the following structure in the response body: `{"error": {"code": "...", "message": "...", "details": [...]}, "meta": {...}}` . The `request_id` is used to enable request traceability through the entire system, and is assigned by the `CorrelationIdFilter` middleware.

5.1.5. Constructor Injection Pattern

All the dependencies are wired up at application startup time, when the application starts up via the main function in `main.cpp`. The Drogon server uses a declarative method system to register its controllers, but each controller's constructor resolves the dependencies of that controller object by constructing the dependency graph for that object.

For example, the constructor for the `TargetController` class constructs a `TargetService` object. The `TargetService` class constructor obtains the `MastClient`, `FitsParser`, `PostgresTargetRepository`, `PostgresTessObservationRepository`, `PostgresLightCurvePointRepository` and `DrogonUuidGenerator` classes, each as a `std::shared_ptr` to the appropriate interface type. There is no service locator system within the application, and there is no runtime dependency injection system to construct these objects at runtime.

The services are implemented using `std::shared_ptr` rather than `std::unique_ptr` because some of the services share some of the repository objects. For example, both the `TargetService` and the `LightCurveComparisonService` objects require access to the `ITargetRepository` and `ITessObservationRepository` interface types, so they both use the same shared instances of those repository classes.

5.2. Directory Structure

The source tree mirrors the architecture layers described above:

```
src/

```

The `core/` directory is separate from `domain/` because it contains cross-cutting utilities (error types, logging, validation) that are used by all layers. The `core/error/AppError.hpp` header defines the `Result<T>` type alias (`std::expected<T, AppError>` (cppreference.com, 2024)), the `ErrorCode` enumeration (13 error codes mapping to HTTP status codes 400–500), and factory methods (`AppError::validation()`, `AppError::not_found()`, `AppError::internal()`, etc.) that standardise error construction across the codebase.

5.3. Database Schema Design

The database consists of 18 tables managed by 18 goose migration files (The PostgreSQL Global Development Group, 2024). Tables are grouped into four domains: authentication, targets, equipment, and observations. Figure 3 shows the entity-relationship diagram.

Entity-relationship diagram — 18 tables across four domains. users ← refresh_tokens, verification_tokens. targets ← tess_observations ← light_curve_points. users ← telescopes, cameras, mounts, filters, observing_locations. users ← observation_sessions ← observation_images. observation_sessions references targets and all equipment tables.

Figure 3: Entity-relationship diagram of the Nyx database schema.

5.3.1. Authentication Domain

The authentication domain manages user accounts, refresh tokens for session management, and email verification tokens.

users table:

```
CREATE TABLE users (  
  id UUID PRIMARY KEY,  
  email VARCHAR(255) NOT NULL UNIQUE,  
  password_hash VARCHAR(255),  
  display_name VARCHAR(100),  
  email_verified BOOLEAN NOT NULL DEFAULT FALSE,  
  auth_provider VARCHAR(20) NOT NULL DEFAULT 'local',  
  google_id VARCHAR(255),  
  created_at TIMESTAMPTZ NOT NULL DEFAULT NOW(),  
  updated_at TIMESTAMPTZ NOT NULL DEFAULT NOW()  
);
```

```
CREATE INDEX idx_users_email ON users(email);  
CREATE UNIQUE INDEX idx_users_google_id  
  ON users(google_id) WHERE google_id IS NOT NULL;
```

The password_hash column is nullable to support OAuth-only accounts where no password is set. The auth_provider column distinguishes between 'local' (email/password) and 'google' (OAuth) accounts. The partial unique index on google_id ensures that each Google account maps to at most one Nyx user, while allowing multiple rows with NULL

Google IDs (the default for local accounts). This is more space-efficient than a standard unique constraint, which would require a sentinel value for non-Google users.

refresh_tokens table:

```
CREATE TABLE refresh_tokens (  
  id UUID PRIMARY KEY,  
  user_id UUID NOT NULL REFERENCES users(id) ON DELETE CASCADE,  
  token_hash VARCHAR(255) NOT NULL UNIQUE,  
  family_id UUID NOT NULL,  
  is_revoked BOOLEAN NOT NULL DEFAULT FALSE,  
  expires_at TIMESTAMPTZ NOT NULL,  
  created_at TIMESTAMPTZ NOT NULL DEFAULT NOW()  
);  
  
CREATE INDEX idx_refresh_tokens_user_id ON refresh_tokens(user_id);  
CREATE INDEX idx_refresh_tokens_family_id ON refresh_tokens(family_id);  
CREATE INDEX idx_refresh_tokens_token_hash ON refresh_tokens(token_hash);
```

The token_hash column stores the SHA-256 hash of the raw refresh token — the raw token is never persisted. The family_id groups all tokens in a rotation chain. When a token is refreshed, a new token is created with the same family_id, and the old token's is_revoked flag is set to TRUE. If a previously revoked token is presented (indicating token theft), all tokens sharing the family_id are revoked. The token_hash index enables O(1) lookup during the refresh flow. The family_id index enables efficient bulk revocation of an entire token family.

verification_tokens table:

```
CREATE TABLE verification_tokens (  
  id UUID PRIMARY KEY,  
  user_id UUID NOT NULL REFERENCES users(id) ON DELETE CASCADE,  
  token_hash VARCHAR(255) NOT NULL UNIQUE,  
  expires_at TIMESTAMPTZ NOT NULL,  
  used_at TIMESTAMPTZ,  
  created_at TIMESTAMPTZ NOT NULL DEFAULT NOW()  
);  
  
CREATE INDEX idx_verification_tokens_user_id  
  ON verification_tokens(user_id);  
CREATE INDEX idx_verification_tokens_token_hash  
  ON verification_tokens(token_hash);
```

Like refresh tokens, verification tokens are stored as SHA-256 hashes. The used_at column is set when the token is consumed, preventing reuse. Expired or used tokens are retained for auditing rather than deleted.

5.3.2. Target Domain

The target domain stores resolved astronomical targets, their TESS observation metadata, and the parsed light curve time-series data.

targets table:

```
CREATE TABLE targets (  
  id UUID PRIMARY KEY,  
  canonical_name VARCHAR(255) NOT NULL UNIQUE,  
  target_type VARCHAR(50),  
  right_ascension DOUBLE PRECISION,  
  declination DOUBLE PRECISION,  
  created_at TIMESTAMPTZ NOT NULL DEFAULT NOW()  
);
```

The `canonical_name` is the MAST-resolved name (e.g. “HAT-P-7” rather than the user’s input “hatp7” or “HAT-P-7b”). The unique constraint ensures that repeated resolution of the same target returns the cached record rather than creating duplicates. Right ascension and declination are stored as `DOUBLE PRECISION` in degrees, matching the MAST API coordinate system. Both are nullable because name resolution occasionally succeeds without returning coordinates (rare, but the schema must tolerate it).

tess_observations table:

```
CREATE TABLE tess_observations (  
  id UUID PRIMARY KEY,  
  target_id UUID NOT NULL REFERENCES targets(id)  
    ON DELETE CASCADE,  
  obsid VARCHAR(20) NOT NULL UNIQUE,  
  cadence_seconds INTEGER NOT NULL,  
  start_time DOUBLE PRECISION NOT NULL,  
  end_time DOUBLE PRECISION NOT NULL,  
  data_uri VARCHAR(500),  
  created_at TIMESTAMPTZ NOT NULL DEFAULT NOW(),  
  updated_at TIMESTAMPTZ NOT NULL DEFAULT NOW()  
);  
  
CREATE INDEX idx_tess_observations_target_id  
  ON tess_observations(target_id);
```

The `obsid` column carries a `UNIQUE` constraint. This is the MAST-assigned observation identifier and serves as the natural key for idempotent ingestion: when the pipeline re-runs for a target that already has observations in the database, the service queries `find_existing_obsids()` with the list of obsids returned by MAST and skips any that already exist. This approach avoids `ON CONFLICT` clauses and gives the application full control over what constitutes a “new” observation.

The `start_time` and `end_time` columns store Modified Julian Dates (MJD) as `DOUBLE PRECISION` values. MJD was chosen over `TIMESTAMPTZ` because the MAST API returns observation time bounds as MJD floats, and storing them in the same format avoids lossy conversion. The `data_uri` column is nullable because it is populated in a separate pipeline stage (product discovery) after the observation record is initially created during the observation search stage.

light_curve_points table:

```
CREATE TABLE light_curve_points (  
  id BIGSERIAL PRIMARY KEY,  
  tess_observation_id UUID NOT NULL  
    REFERENCES tess_observations(id) ON DELETE CASCADE,  
  time DOUBLE PRECISION NOT NULL,  
  pdcsap_flux REAL,  
  pdcsap_flux_err REAL,  
  sap_flux REAL,  
  quality INTEGER NOT NULL DEFAULT 0  
);  
  
CREATE INDEX idx_lcp_observation_id  
  ON light_curve_points(tess_observation_id);  
CREATE INDEX idx_lcp_observation_time  
  ON light_curve_points(tess_observation_id, time);
```

This table stores the parsed FITS light curve data. A single TESS observation sector contains approximately 18,000 to 20,000 data points at 2-minute cadence, or approximately 600 to 700 points at 30-minute cadence. For a target observed across 10 sectors, this amounts to roughly 180,000 to 200,000 rows. At scale (hundreds of targets), the table could reach tens of millions of rows.

The primary key uses BIGSERIAL rather than UUID for two reasons. First, the auto-incrementing integer avoids the 16-byte storage overhead of UUID per row, which matters when the table contains millions of rows with narrow columns (the entire row is approximately 40 bytes excluding the UUID overhead). Second, BIGSERIAL produces naturally ordered keys that align with B-tree index leaf page ordering, reducing page splits during sequential inserts (Winand, 2012).

The time column stores Barycentric TESS Julian Date (BTJD) as DOUBLE PRECISION. The pdcsap_flux, pdcsap_flux_err, and sap_flux columns use REAL (4-byte single-precision float) rather than DOUBLE PRECISION because the source FITS data stores these columns as 32-bit floats, and there is no information gain from widening to 64 bits. The quality column is an integer bitmask defined by the TESS SPOC pipeline (Jenkins *et al.*, 2016); a value of zero means no known data quality issues.

The composite index idx_lcp_observation_time on (tess_observation_id, time) is the most performance-critical index in the schema. It supports the primary query pattern: retrieve all light curve points for a given observation, ordered by time. Because tess_observation_id is the leading column, PostgreSQL can use an index-only scan (if the query selects only indexed columns) or an index scan with a single seek followed by a sequential read of the leaf pages. The ORDER BY time ASC clause in the query aligns with the index sort order, so no in-memory sort is required (Winand, 2012).

5.3.3. Equipment Domain

The equipment domain stores user-owned astronomical equipment.

telescopes table:

```
CREATE TABLE telescopes (  
  id UUID PRIMARY KEY,  
  user_id UUID NOT NULL REFERENCES users(id)  
    ON DELETE CASCADE,  
  name VARCHAR(255) NOT NULL,  
  aperture_mm INTEGER NOT NULL,  
  focal_length_mm INTEGER NOT NULL,  
  optical_design VARCHAR(50) NOT NULL,  
  brand VARCHAR(255),  
  model VARCHAR(255),  
  created_at TIMESTAMPTZ NOT NULL DEFAULT NOW(),  
  updated_at TIMESTAMPTZ NOT NULL DEFAULT NOW()  
);  
  
CREATE INDEX idx_telescopes_user_id ON telescopes(user_id);
```

cameras table:

```
CREATE TABLE cameras (  
  id UUID PRIMARY KEY,  
  user_id UUID NOT NULL REFERENCES users(id)  
    ON DELETE CASCADE,  
  name VARCHAR(255) NOT NULL,  
  sensor_type VARCHAR(50) NOT NULL,  
  brand VARCHAR(255),  
  model VARCHAR(255),  
  pixel_size_um DOUBLE PRECISION,  
  resolution VARCHAR(50),  
  created_at TIMESTAMPTZ NOT NULL DEFAULT NOW(),  
  updated_at TIMESTAMPTZ NOT NULL DEFAULT NOW()  
);  
  
CREATE INDEX idx_cameras_user_id ON cameras(user_id);
```

mounts table:

```
CREATE TABLE mounts (  
  id UUID PRIMARY KEY,  
  user_id UUID NOT NULL REFERENCES users(id)  
    ON DELETE CASCADE,  
  name VARCHAR(255) NOT NULL,  
  mount_type VARCHAR(50) NOT NULL,  
  is_tracked BOOLEAN NOT NULL DEFAULT FALSE,  
  has_goto BOOLEAN NOT NULL DEFAULT FALSE,  
  brand VARCHAR(255),  
  model VARCHAR(255),  
  created_at TIMESTAMPTZ NOT NULL DEFAULT NOW(),  
  updated_at TIMESTAMPTZ NOT NULL DEFAULT NOW()  
);
```

```
CREATE INDEX idx_mounts_user_id ON mounts(user_id);
```

filters table:

```
CREATE TABLE filters (  
  id UUID PRIMARY KEY,  
  user_id UUID NOT NULL REFERENCES users(id)  
    ON DELETE CASCADE,  
  name VARCHAR(255) NOT NULL,  
  band VARCHAR(50) NOT NULL,  
  bandwidth_nm DOUBLE PRECISION,  
  brand VARCHAR(255),  
  model VARCHAR(255),  
  created_at TIMESTAMPTZ NOT NULL DEFAULT NOW(),  
  updated_at TIMESTAMPTZ NOT NULL DEFAULT NOW()  
);
```

```
CREATE INDEX idx_filters_user_id ON filters(user_id);
```

All equipment tables share the same structural pattern: UUID primary key, foreign key to users(id) with ON DELETE CASCADE, a user-assigned name, type-specific attributes, and timestamps. A unique index on (user_id, name) is applied to observing locations (and could be extended to equipment tables) to prevent a user from creating two items with the same name.

5.3.4. Observation Domain

The observation domain links ground-based observations to targets and equipment.

observing_locations table:

```
CREATE TABLE observing_locations (  
  id UUID PRIMARY KEY,  
  user_id UUID NOT NULL REFERENCES users(id)  
    ON DELETE CASCADE,  
  name VARCHAR(255) NOT NULL,  
  latitude DOUBLE PRECISION NOT NULL,  
  longitude DOUBLE PRECISION NOT NULL,  
  bortle_class SMALLINT,  
  created_at TIMESTAMPTZ NOT NULL DEFAULT NOW(),  
  updated_at TIMESTAMPTZ NOT NULL DEFAULT NOW()  
);
```

```
CREATE INDEX idx_observing_locations_user_id  
ON observing_locations(user_id);
```

```
CREATE UNIQUE INDEX idx_observing_locations_user_id_name  
ON observing_locations(user_id, name);
```

The bortle_class column uses SMALLINT (1–9 scale) to record the sky brightness at the location. The unique index on (user_id, name) prevents duplicate location names per user,

returning a 409 Conflict error at the database level rather than requiring an application-level check.

observation_sessions table:

```
CREATE TABLE observation_sessions (  
  id UUID PRIMARY KEY,  
  user_id UUID NOT NULL REFERENCES users(id)  
    ON DELETE CASCADE,  
  target_id UUID NOT NULL REFERENCES targets(id),  
  telescope_id UUID NOT NULL REFERENCES telescopes(id),  
  camera_id UUID NOT NULL REFERENCES cameras(id),  
  mount_id UUID NOT NULL REFERENCES mounts(id),  
  location_id UUID NOT NULL  
    REFERENCES observing_locations(id),  
  filter_id UUID REFERENCES filters(id),  
  notes TEXT,  
  created_at TIMESTAMPTZ NOT NULL DEFAULT NOW(),  
  updated_at TIMESTAMPTZ NOT NULL DEFAULT NOW()  
);  
  
CREATE INDEX idx_observation_sessions_user_id  
  ON observation_sessions(user_id);  
CREATE INDEX idx_observation_sessions_target_id  
  ON observation_sessions(target_id);
```

The session table links a user, a target, and the complete equipment configuration used for the observation. The `filter_id` column is the only nullable equipment reference, because unfiltered observations are common in amateur astronomy. All other equipment references are NOT NULL because a meaningful ground-based observation requires at minimum a telescope, camera, mount, and location.

observation_images table:

```
CREATE TABLE observation_images (  
  id UUID PRIMARY KEY,  
  session_id UUID NOT NULL  
    REFERENCES observation_sessions(id) ON DELETE CASCADE,  
  filename VARCHAR(255) NOT NULL,  
  original_filename VARCHAR(255) NOT NULL,  
  file_path VARCHAR(1024) NOT NULL,  
  file_size_bytes BIGINT NOT NULL,  
  mime_type VARCHAR(50) NOT NULL,  
  captured_at TIMESTAMPTZ,  
  camera_model VARCHAR(255),  
  exposure_time_seconds DOUBLE PRECISION,  
  iso_speed INTEGER,  
  gps_latitude DOUBLE PRECISION,  
  gps_longitude DOUBLE PRECISION,  
  image_width INTEGER,  
  image_height INTEGER,
```

```

target_x INTEGER,
target_y INTEGER,
raw_flux DOUBLE PRECISION,
raw_flux_error DOUBLE PRECISION,
relative_flux DOUBLE PRECISION,
relative_flux_error DOUBLE PRECISION,
photometry_status VARCHAR(20),
photometry_error_message TEXT,
created_at TIMESTAMPTZ NOT NULL DEFAULT NOW()
);

CREATE INDEX idx_observation_images_session_id
ON observation_images(session_id);

```

The image table stores both the file metadata and the EXIF-extracted metadata (first group of nullable columns: `captured_at` through `image_height`) and the photometry results (second group: `target_x` through `photometry_error_message`). The `filename` column stores a UUID-based name generated on upload to avoid filesystem collisions; `original_filename` preserves the name the user uploaded. The `photometry_status` column can be 'pending', 'completed', or 'failed', tracking the state of the asynchronous photometry pipeline. When photometry fails, `photometry_error_message` records the reason.

5.3.5. Why PostgreSQL

PostgreSQL (The PostgreSQL Global Development Group, 2024) was chosen over specialised time-series databases (TimescaleDB (Timescale, Inc., 2024), InfluxDB) for three reasons. First, the data volume — tens of millions of light curve points at most — is well within PostgreSQL’s capability when properly indexed. TimescaleDB’s hypertable partitioning provides significant benefit only at billions of rows or when time-range deletions (chunk dropping) are frequent; neither condition applies here. Second, the system requires relational modelling beyond time-series: users, sessions, equipment, tokens, and images all have complex relationships with foreign keys and join requirements that relational databases handle natively but time-series databases handle poorly or not at all. Third, using a single database engine simplifies deployment, backup, monitoring, and developer onboarding. The composite index (`tess_observation_id`, `time`) provides the range-scan performance that a hypertable would otherwise offer, as confirmed by query plan analysis in Section 7.

5.4. API Design

All endpoints are versioned under `/api/v1`, following Fielding’s REST architectural style (Fielding, 2000). Resource names use plural nouns with hyphens for multi-word names (e.g. `/observation-sessions`, `/tess-observations`). HTTP methods map to operations: GET for retrieval, POST for creation and actions, PUT for full replacement, DELETE for removal. Actions that do not fit the CRUD model use POST on a sub-resource (e.g. POST `/tess-observations/:id/discover-products`).

Table 2 lists all 28 endpoints.

Method	Route	Auth	Description
Authentication			
POST	/auth/register	No	Register with email and password
POST	/auth/login	No	Login, returns access token
POST	/auth/refresh	Cookie	Refresh access token
POST	/auth/logout	Cookie	Revoke refresh token
POST	/auth/verify-email	No	Verify email address
POST	/auth/resent-verification	No	Resend verification email
POST	/auth/google	No	Google OAuth2 code exchange
Profile			
PUT	/users/me/profile	JWT	Complete onboarding profile
Targets			
POST	/targets/resolve	No	Resolve target name via MAST
GET	/targets/:id	No	Get target with observations
GET	/targets/:id/tess-observations	No	List TESS observations
GET	/targets/:id/light-curve-comparison	JWT	Compare TESS and user data
TESS Observations			
POST	/tess-observations/:id/discover-products	No	Discover FITS products
POST	/tess-observations/:id/fetch-light-curve	No	Download and parse FITS
GET	/tess-observations/:id/light-curve	No	Get stored light curve
Equipment (CRUD – each resource)			
POST	/telescopes	JWT+CSRF	Create telescope
GET	/telescopes	JWT	List user's telescopes
GET	/telescopes/:id	JWT	Get telescope
PUT	/telescopes/:id	JWT+CSRF	Update telescope
DELETE	/telescopes/:id	JWT+CSRF	Delete telescope
<i>(Cameras, Mounts, Filters follow the same CRUD pattern)</i>			

Table 2: Complete API endpoint listing. “JWT” means the JWTAuthFilter is applied. “JWT+CSRF” means the CsrfFilter is additionally applied. “Cookie” means the refresh token is read from an HttpOnly cookie.

5.4.1. Response Envelope

All responses use a consistent JSON envelope. Successful responses:

```
{
  "data": {
    "id": "550e8400-e29b-41d4-a716-446655440000",
    "canonical_name": "HAT-P-7",
    "target_type": "Star",
    "right_ascension": 292.45638,
    "declination": 47.96946
  },
  "meta": {
    "request_id": "a3b2c1d0-...",
    "timestamp": "2026-04-05T14:30:00"
  }
}
```

Error responses replace data with error:

```
{
  "error": {
    "code": "VALIDATION_ERROR",
    "message": "Invalid request body",
    "details": [
      { "field": "email", "message": "must be a valid email" },
      { "field": "password", "message": "must be at least 8 characters" }
    ]
  },
  "meta": {
    "request_id": "a3b2c1d0-...",
    "timestamp": "2026-04-05T14:30:00"
  }
}
```

The `meta.request_id` field carries the correlation ID generated by the `CorrelationIdFilter` middleware. This ID appears in every log line produced during the request, enabling end-to-end tracing from the client through the controller, service, and repository layers. The `details` array is populated only for validation errors and contains per-field error messages. Server errors (5xx) never expose internal details to clients — the service logs the full error context internally and returns a generic `"INTERNAL_ERROR"` message.

The `AppError` struct defines 13 error codes that map to HTTP status codes:

Error Code	HTTP Status	Usage
VALIDATION_ERROR	400	Invalid input data
INVALID_JSON	400	Malformed JSON body
AUTHENTICATION_REQUIRED	401	Missing or invalid credentials
INVALID_TOKEN	401	Malformed or tampered JWT
TOKEN_EXPIRED	401	Expired JWT
PERMISSION_DENIED	403	CSRF failure or access denied
EMAIL_NOT_VERIFIED	403	Unverified email address
RESOURCE_NOT_FOUND	404	Entity not found
CONFLICT	409	Duplicate resource
RATE_LIMIT_EXCEEDED	429	Too many requests
INTERNAL_ERROR	500	Unrecoverable server error
DATABASE_ERROR	500	Database failure
EXTERNAL_SERVICE_ERROR	500	MAST API or external call failure

Table 3: Error code to HTTP status code mapping.

5.4.2. Pagination

The API does not implement cursor-based pagination. At the current scale — a user typically has fewer than 50 equipment items, fewer than 100 observation sessions, and a target typically has fewer than 30 TESS observations — all list endpoints return complete result sets. The light curve endpoint, which can return tens of thousands of points, uses a streaming JSON approach (PostgreSQL’s `json_agg` constructs the JSON array server-side in a single query) rather than pagination, since the frontend needs all data points to render the complete light curve. If the platform scales to thousands of users with large observation histories, pagination would be added to the session and equipment list endpoints as offset-based pagination (simpler to implement for infrequently-changing datasets) rather than cursor-based.

5.5. Data Ingestion Pipeline Design

The TESS data ingestion pipeline is a four-stage ETL process that transforms a user-provided target name into a set of persisted light curve time-series records. The pipeline is implemented in `TargetService` and `TessObservationController`, with the MAST API communication delegated to `IMastClient` and the FITS parsing delegated to `IFitsParser`. Figure 4 illustrates the stages.

Pipeline flow diagram — Stage 1: Name Resolution (Mast.Name.Lookup) → Stage 2: Observation Search (Mast.Caom.Filtered.Position) → Stage 3: Product Discovery (Mast.Caom.Products) → Stage 4: FITS Download and Parse (HTTP GET + CFITSIO). Each stage shows input, API call, and persisted output.

Figure 4: Four-stage TESS data ingestion pipeline.

5.5.1. Stage 1: Name Resolution

The user provides a target name (e.g. “HAT-P-7”, “pi Mensae”, “TIC 261136679”). The `TargetService::resolve_target()` method first checks whether a target with the same canonical name already exists in the targets table. If it does, the cached record is returned immediately, avoiding a redundant API call.

If the target is not cached, `IMastClient::resolve_target()` calls the MAST `Mast.Name.Lookup` service. The request payload is:

```
{
  "service": "Mast.Name.Lookup",
  "params": { "input": "HAT-P-7", "format": "json" }
}
```

This JSON is serialised, URL-encoded, and sent as the request parameter in a form-encoded POST body to `https://mast.stsci.edu/api/v0/invoke`. The MAST API requires this unusual encoding: it does not accept JSON directly in the request body (Space Telescope Science Institute, 2024).

The response contains a `resolvedCoordinate` array. The first element provides the canonical name, object type, right ascension (ra), and declination (decl). These are extracted and persisted to the targets table.

5.5.2. Stage 2: Observation Search

Using the resolved sky coordinates, `IMastClient::search_tess_timeseries()` calls the MAST `Mast.Caom.Filtered.Position` service. The request specifies:

```
{
  "service": "Mast.Caom.Filtered.Position",
  "params": {
    "columns": "obsid,t_exptime,t_min,t_max",
    "filters": [
      { "paramName": "obs_collection", "values": ["TESS"] },

```

```

    { "paramName": "dataproduct_type", "values": ["timeseries"] }
  ],
  "position": "292.45638, 47.96946, 0.005",
  "format": "json"
}
}

```

The position parameter is a comma-separated string of ra, dec, radius in degrees. The 0.005-degree radius (approximately 18 arcseconds) is tight enough to avoid matching nearby stars while accommodating TESS's relatively large pixel scale (21 arcseconds per pixel) (Ricker *et al.*, 2015).

The response uses the MAST columnar format: a Tables array containing a single table object with Fields (column definitions) and Rows (arrays of values). This is not row-oriented JSON — each row is a positional array whose element ordering matches the Fields array. The MastClient must therefore first scan the Fields array to locate the column indices for obsid, t_exptime, t_min, and t_max, then iterate over the Rows array and extract values by index. This reconstructs row-oriented records from the columnar response.

The pipeline applies a multi-sector filter at this stage. If an observation's time span ($t_{\max} - t_{\min}$) exceeds 30 days, it is classified as a multi-sector combined observation and skipped. Multi-sector observations duplicate data from individual sectors and would lead to redundant light curve points. Only single-sector observations (approximately 27 days each) are retained.

The pipeline then performs idempotent re-ingestion. It calls `find_existing_obsids()` with the list of obsids from the MAST response. This method executes a single `SELECT obsid FROM tess_observations WHERE obsid = ANY($1)` query and returns a set of already-persisted obsids. The pipeline inserts only observations whose obsids are not in this set, then bulk-inserts the new records via `bulk_create()`.

5.5.3. Stage 3: Product Discovery

Stages 1 and 2 execute together when a target is first resolved. Stage 3 executes separately, triggered by a `POST /tess-observations/:id/discover-products` request for a specific observation.

The `TargetService::discover_products()` method first checks whether the observation already has a `data_uri`. If it does, the cached value is returned. Otherwise, `IMastClient::get_data_products()` calls the MAST `Mast.Caom.Products` service:

```

{
  "service": "Mast.Caom.Products",
  "params": { "obsid": "428836211", "format": "json" }
}

```

The response uses the same columnar format. The pipeline locates the `dataURI`, `description`, `productType`, and `productFilename` columns, then filters for the light curve FITS file. The filter criteria are:

1. `description` equals "Light curves"
2. `productType` equals "SCIENCE"
3. `filename` ends with `"_lc.fits"`

The first matching product's `dataURI` is stored in the `data_uri` column of the `tess_observations` table via `update_data_uri()`.

5.5.4. Stage 4: FITS Download and Parse

Stage 4 is triggered by a `POST /tess-observations/:id/fetch-light-curve` request. The `TargetService::fetch_light_curve()` method first checks whether light curve points already exist for the observation (via `count_by_observation_id()`). If they do, the cached metadata is returned.

Otherwise, `IMastClient::download_fits()` sends an HTTP GET request to `https://mast.stsci.edu/api/v0.1/Download/file?uri=<data_uri>`. MAST responds with either the FITS binary data directly (HTTP 200) or an HTTP redirect (301, 302, or 307) to a CDN URL. The `MastClient` handles redirects manually: it parses the `Location` header, extracts the host and path, creates a new HTTP client for the redirect host, and sends a second GET request.

The downloaded binary data is passed to `IFitsParser::parse_light_curve()`, which extracts the light curve columns as described in Section 5.6. The resulting `LightCurvePoint` records are bulk-inserted into the `light_curve_points` table in batches of 5,000 rows within a single database transaction.

5.5.5. Caching Strategy

The pipeline uses PostgreSQL as its sole cache layer — there is no Redis, Memcached, or other intermediary. The caching is layered:

1. **Target-level cache:** `find_by_canonical_name()` returns the existing target record, skipping Stage 1 entirely.
2. **Observation-level cache:** `find_existing_obsids()` identifies which observations are already persisted, skipping them during Stage 2 bulk insert.
3. **Product-level cache:** the `data_uri` column on `tess_observations` records whether Stage 3 has run. A non-null `data_uri` causes `discover_products()` to return immediately.
4. **Light curve-level cache:** `count_by_observation_id()` checks whether Stage 4 has run. A positive count causes `fetch_light_curve()` to return the stored metadata.

This design means that the first resolution of a new target triggers MAST API calls, but all subsequent requests for the same target are served entirely from PostgreSQL. Re-ingestion (fetching new observations for an existing target) is supported by re-resolving the target: the pipeline detects the cached target, re-queries MAST for observations, and inserts only genuinely new ones.

5.6. FITS File Format and Parsing Design

The Flexible Image Transport System (FITS) is the standard file format for astronomical data (Pence *et al.*, 2010). TESS light curve FITS files are produced by the Science Processing Operations Center (SPOC) pipeline (Jenkins *et al.*, 2016; Tenenbaum and Jenkins, 2018) and distributed via MAST.

5.6.1. FITS File Structure

A TESS light curve FITS file (`*_lc.fits`) contains multiple Header Data Units (HDUs):

- **Primary HDU (HDU 1):** A header-only unit containing metadata about the observation (target name, TESS Input Catalog ID, sector number, camera, CCD, observation dates). No image or table data.
- **Binary Table Extension (HDU 2):** The light curve data as a binary table with one row per cadence. This is the HDU that the parser reads.
- **Additional HDUs:** Aperture pixel mask and other auxiliary data. Not used by Nyx.

Figure 5 illustrates the layout.

FITS file structure diagram — HDU 1 (Primary): header keywords only. HDU 2 (Binary Table Extension): TIME, SAP_FLUX, PDCSAP_FLUX, PDCSAP_FLUX_ERR, QUALITY columns, one row per cadence (18,000 rows at 2-min cadence). HDU 3+: aperture mask, auxiliary data (not used).

Figure 5: Structure of a TESS light curve FITS file.

5.6.2. Light Curve Columns

The binary table in HDU 2 contains the following columns relevant to Nyx:

- **TIME** (DOUBLE PRECISION): Barycentric TESS Julian Date (BTJD), defined as BJD — 2457000.0 (Eastman, Siverd and Gaudi, 2010). This is the time axis of the light curve.
- **SAP_FLUX** (FLOAT): Simple Aperture Photometry flux in electrons per second. This is the raw sum of pixel values within the optimal aperture, after background subtraction. It contains instrumental systematics (spacecraft pointing jitter, thermal drift, scattered light) that produce trends and discontinuities unrelated to the target’s intrinsic variability.
- **PDCSAP_FLUX** (FLOAT): Pre-search Data Conditioning SAP flux. This is the SAP flux after correction for systematic effects using cotrending basis vectors derived from quiet stars on the same CCD (Stumpe *et al.*, 2012). PDCSAP flux is the standard data product

for transit detection and variable star analysis because the dominant instrumental signals have been removed.

- **PDCSAP_FLUX_ERR** (FLOAT): The 1-sigma uncertainty on the PDCSAP flux, propagated from the photon noise, readout noise, and background estimation uncertainty.
- **QUALITY** (INTEGER): A bitmask encoding data quality flags. Each bit indicates a specific anomaly (e.g. spacecraft attitude tweak, cosmic ray, momentum dump). A value of 0 means no known quality issues. The frontend allows toggling a quality filter that hides points with non-zero quality flags.

5.6.3. CFITSIO Parsing Implementation

The `FitsParser` class implements the `IFitsParser` interface. CFITSIO is a C library that requires file-based access — it has no API for reading FITS data from an in-memory buffer. The parser therefore uses a temporary file approach:

1. Create a temporary file with `mkstemp("/tmp/nyx_fits_XXXXXX")`.
2. Write the FITS binary data (received as a `std::string` from the HTTP download) to the file descriptor.
3. Close the file descriptor.
4. Open the file with CFITSIO's `fits_open_file()`.
5. Move to HDU 2 with `fits_movabs_hdu()`.
6. Query the number of rows with `fits_get_num_rows()`.
7. Locate each column by name with `fits_get_colnum()` (case-insensitive).
8. Read each column into a pre-allocated `std::vector` with `fits_read_col()`.
9. Close the file with `fits_close_file()`.
10. Delete the temporary file.

Cleanup is guaranteed by the `FitsFileGuard` RAII class, which calls `std::remove()` on the temporary file in its destructor. This ensures the file is deleted even if an exception is thrown during parsing.

5.6.4. NaN Handling

FITS uses IEEE 754 NaN (Not a Number) as the standard representation for missing or undefined values. This is different from SQL NULL and must be handled explicitly. The parser checks each value with `std::isnan()`:

- If `TIME` is NaN, the entire row is skipped (a data point without a timestamp is useless).
- If `PDCSAP_FLUX`, `PDCSAP_FLUX_ERR`, or `SAP_FLUX` is NaN, the corresponding field is set to `std::nullopt` in the `LightCurvePoint` struct. The PostgreSQL repository serialises `std::nullopt` as an empty string, which is then cast to NULL via `CAST(NULLIF($n, '') AS REAL)` in the parameterised INSERT statement.

This approach preserves partial data: a point with a valid time and SAP flux but a NaN PDCSAP flux is still useful for analysis.

5.6.5. Column Reading Strategy

The parser reads all rows for each column in a single `fits_read_col()` call rather than reading one row at a time. This is significantly more efficient because CFITSIO can read contiguous blocks from the binary table in a single I/O operation, whereas row-by-row access would require repeated seeking. For a typical 2-minute cadence observation with approximately 18,000 rows, this means 5 bulk column reads rather than 90,000 individual cell reads.

5.7. Image Processing and Photometry Design

The image processing subsystem handles ground-based observation images uploaded by users. It consists of three stages: EXIF metadata extraction, optional DNG raw image decoding, and aperture photometry. These stages are modelled as three application-layer interfaces with infrastructure-layer implementations.

5.7.1. EXIF Metadata Extraction

The `IExifParser` interface declares a single method:

```
parse(file_path) -> Result<ExifData>
```

The `ExifData` struct contains eight optional fields extracted from the image's EXIF headers:

- `captured_at` — the timestamp when the image was taken (from `Exif.Photo.DateTimeOriginal`).
- `camera_model` — the camera body model (from `Exif.Image.Model`).
- `exposure_time_seconds` — the exposure duration (from `Exif.Photo.ExposureTime`).
- `iso_speed` — the ISO sensitivity (from `Exif.Photo.ISOSpeedRatings`).
- `gps_latitude` and `gps_longitude` — the geographic coordinates (from `Exif.GPSInfo.GPSLatitude` and `GPSLongitude`).
- `image_width` and `image_height` — the pixel dimensions (from `Exif.Photo.PixelXDimension` and `PixelYDimension`).

All fields are optional because different cameras populate different subsets of the EXIF specification. The `Exiv2ExifParser` implementation uses the `Exiv2` library to read these fields, handling missing tags gracefully by returning `std::nullopt`.

The extracted metadata is persisted directly to the `observation_images` table. The `captured_at` timestamp is particularly important because it provides the time axis for ground-based light curve construction: each image's capture time, combined with its measured flux, forms one data point.

5.7.2. DNG Raw Image Decoding

The `IDngDecoder` interface declares:

```
decode(file_path) -> Result<DecodedImage>
```

The `DecodedImage` struct contains a `std::vector<uint16_t>` pixel array plus width, height, and channel count. Raw DNG images preserve the linear sensor response (unlike processed JPEG images that apply gamma correction, white balance, and compression), making them suitable for photometric analysis. The `LibrawDngDecoder` implementation uses the `LibRaw` library to demosaic the Bayer-pattern sensor data into a linear RGB image.

5.7.3. Aperture Photometry Algorithm

The `IPhotometryProcessor` interface declares two methods:

```
detect_sources(image, threshold_sigma) -> vector<DetectedSource>
measure_aperture(image, center_x, center_y,
    aperture_radius, annulus_inner_radius,
    annulus_outer_radius) -> Result<PhotometryResult>
```

The `AperturePhotometer` implementation performs aperture photometry following standard practices in amateur exoplanet observation (Gary, 2007; Conti and Conti, 2018):

1. **Source detection:** The algorithm computes the mean and standard deviation of pixel values across the image. Pixels exceeding the mean by more than `threshold_sigma` standard deviations are candidate source pixels. Connected components of candidate pixels are grouped, and the centroid of each group yields a `DetectedSource` with (x, y) coordinates and a `peak_value`.
2. **Aperture definition:** A circular aperture of radius `aperture_radius` pixels is centred on the target star's coordinates (`center_x`, `center_y`).
3. **Background estimation:** An annulus between `annulus_inner_radius` and `annulus_outer_radius` (both larger than the aperture radius) provides a sample of the local sky background. The median pixel value within the annulus is taken as the background estimate, which is more robust to contamination by faint stars than the mean.
4. **Flux calculation:** The raw flux is the sum of pixel values within the circular aperture minus the product of the background estimate and the aperture area (number of pixels within the aperture). In notation: $F_{\text{raw}} = \sum_{i \in \text{aperture}} p_i - B_{\text{sky}} \cdot A$, where p_i is the pixel value, B_{sky} is the median background, and A is the aperture area.
5. **Error estimation:** The flux error combines three noise sources: Poisson noise from the source ($\sqrt{\frac{F_{\text{raw}}}{g}}$ where g is the gain), readout noise ($\sigma_{\text{read}}^2 \cdot A$), and background noise ($\sigma_{\text{sky}}^2 \cdot A$). The total error is the square root of the sum of these variances.

The `PhotometryResult` contains `raw_flux` and `raw_flux_error`. The relative flux (normalised to a reference star or the mean) is computed by the `ObservationService` after all images in a session have been measured, and stored in the `relative_flux` and `relative_flux_error` columns of `observation_images`.

The `photometry_status` column tracks the processing state. When a user triggers photometry via `POST /observation-sessions/:id/photometry`, the service sets `photometry_status = 'pending'` for all images, then processes each image sequentially.

On success, the status is updated to 'completed' with the flux values. On failure (e.g. no source detected at the given coordinates, corrupted image file), the status is updated to 'failed' with a diagnostic message in `photometry_error_message`.

5.8. Time System Design

Comparing space-based and ground-based observations requires aligning their timestamps to a common reference frame. Three time systems are relevant to Nyx.

5.8.1. Julian Date (JD)

The Julian Date is the continuous count of days since the beginning of the Julian Period (12:00 UTC, January 1, 4713 BC). It is the universal time system in astronomy because it avoids the discontinuities and ambiguities of calendar-based systems (leap years, month lengths, time zones). For example, 2026-04-05T12:00:00 UTC corresponds to JD 2461402.0.

5.8.2. Barycentric Julian Date (BJD)

The Barycentric Julian Date corrects JD for the light travel time between the observer and the Solar System barycentre (centre of mass). Without this correction, the timestamps of the same event as measured from different locations in Earth's orbit can differ by up to ± 8.3 minutes — the light travel time across 1 AU (Eastman, Siverd and Gaudi, 2010). For transit timing, where the ingress and egress of an exoplanet transit can last only minutes (Winn, 2010), this correction is essential.

BJD is computed from JD by adding the light travel time correction: $BJD = JD + \Delta t_{\text{bary}}$, where Δt_{bary} depends on the observer's position in the Solar System and the sky coordinates of the target. Precise computation requires ephemeris tables (e.g. JPL DE430).

5.8.3. Barycentric TESS Julian Date (BTJD)

TESS light curve timestamps use BTJD, defined as:

$$BTJD = BJD - 2457000.0$$

This offset subtracts a constant to produce smaller, more human-readable numbers. For example, a BJD of 2459580.5 becomes BTJD 2580.5. The offset 2457000.0 corresponds approximately to the J2015.0 epoch.

5.8.4. Ground-Based Timestamp Conversion

Ground-based observations record timestamps in UTC via EXIF metadata (ISO 8601 format). To overlay these on TESS light curves, Nyx must convert UTC to BTJD. The `TimeConversion` utility class implements this conversion:

1. Parse the ISO 8601 string into year, month, day, hour, minute, second.
2. Convert to JD using the standard formula for the Gregorian calendar:

$$JD = \lfloor 365.25(Y + 4716) \rfloor + \lfloor 30.6001(M + 1) \rfloor + D + B - 1524.5 + (H + M/60 + S/3600)/24$$

where Y and M are adjusted for January/February ($Y = Y - 1$, $M = M + 12$ when month ≤ 2), and $B = 2 - \lfloor Y/100 \rfloor + \lfloor Y/400 \rfloor$ is the Gregorian correction.

3. Approximate BJD as JD (the barycentric correction is omitted because it requires ephemeris data and the target's sky coordinates; the resulting error of up to ± 8.3 minutes is acceptable for visual comparison but would need to be addressed for precise transit timing analysis (Hessman, 2004; Eastman, Siverd and Gaudi, 2010)).
4. Convert to BTJD by subtracting the constant offset: $BTJD = BJD - 2457000.0$.

The `LightCurveComparisonService` applies this conversion when assembling the comparison response, placing both TESS and user data points on the same BTJD time axis.

5.9. Authentication Architecture Design

The authentication system implements a dual-token strategy following OAuth 2.0 security best practices (Lodderstedt *et al.*, 2020). It supports two authentication flows: local email/password registration and Google OAuth2 login.

5.9.1. Token Strategy

The system uses two token types with different lifetimes and storage mechanisms:

- **Access token:** A JSON Web Token (Jones, Bradley and Sakimura, 2015) (JWT) signed with HS256 (HMAC-SHA256), containing the user ID and email as claims, with a 15-minute expiry. The short lifetime limits the window of exploitation if the token is stolen. The access token is returned in the JSON response body and stored by the frontend in memory (not in `localStorage` or cookies).
- **Refresh token:** An opaque UUID (not a JWT), with a 7-day expiry. The raw token is sent to the client via an `HttpOnly`, `Secure`, `SameSite=Strict` cookie scoped to the `/api/v1/auth` path. This cookie configuration ensures: (1) JavaScript cannot read the token (`HttpOnly`), (2) it is only sent over HTTPS (`Secure`), (3) it is not sent with cross-origin requests (`SameSite=Strict`), and (4) it is only sent to authentication endpoints (path scoping).

The token is never stored in raw form on the server. Before persistence, it is hashed with SHA-256. The database stores only the hash, so a database breach does not compromise active sessions.

5.9.2. Refresh Token Rotation

When the client's access token expires, it sends `POST /auth/refresh`. The refresh token is automatically included by the browser via the `HttpOnly` cookie. The `AuthService::refresh_access_token()` method:

1. Hashes the presented refresh token.
2. Looks up the token hash in the `refresh_tokens` table.
3. If the token is not found, returns 401 (invalid token).

4. If the token is found but `is_revoked = TRUE`, this indicates token reuse — a potential theft. The service revokes the entire token family (all tokens with the same `family_id`) and returns 401.
5. If the token is found, not revoked, and not expired, the service: a. Marks the current token as revoked (`is_revoked = TRUE`). b. Generates a new access/refresh token pair. c. Stores the new refresh token hash with the same `family_id`. d. Returns the new access token in the response body and sets the new refresh token cookie.

Figure 6 illustrates this flow.

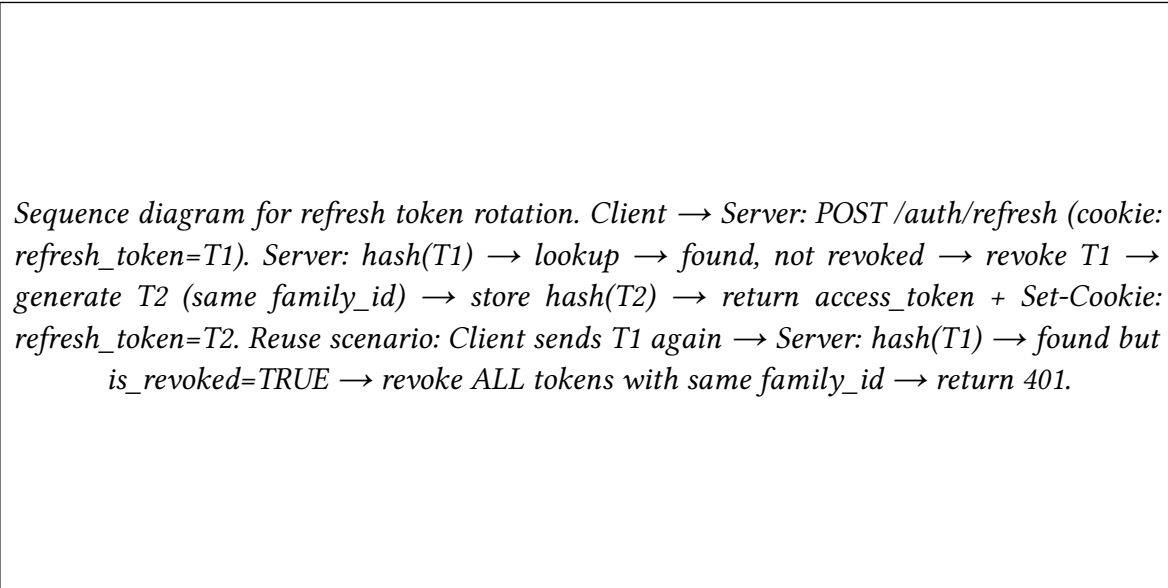

Figure 6: Refresh token rotation with family-based reuse detection.

The family-based reuse detection protects against a specific attack: if an attacker steals refresh token T1 and uses it to obtain T2 before the legitimate client does, the legitimate client’s subsequent use of T1 triggers the reuse alarm and revokes the entire family, including the attacker’s T2. This is the approach recommended by (Lodderstedt *et al.*, 2020).

5.9.3. CSRF Protection

Because the refresh token is stored in a cookie, state-changing requests are vulnerable to Cross-Site Request Forgery (CSRF) (OWASP Foundation, 2024a). Nyx implements the Double Submit Cookie pattern:

1. On login, the server generates a cryptographically random CSRF token and sets it as a non-HttpOnly, Secure, SameSite=Strict cookie (`csrf_token`). The non-HttpOnly flag is intentional — the frontend JavaScript must be able to read this cookie.
2. For every state-changing request (POST, PUT, DELETE), the frontend reads the `csrf_token` cookie and includes its value in the X-CSRF-Token request header.
3. The `CsrfFilter` middleware compares the cookie value against the header value using `sodium_memcmp()` (Bernstein, 2012) for constant-time comparison, preventing timing side-channel attacks.

4. GET, HEAD, and OPTIONS requests are exempt from CSRF validation because they are safe (non-state-changing) methods.

5.9.4. Google OAuth2 Flow

Google login uses the Authorization Code flow (Hardt, 2012; Sakimura *et al.*, 2014):

1. The frontend redirects the user to Google's authorization endpoint with the application's client ID, redirect URI, and requested scopes (openid, email, profile).
2. After the user consents, Google redirects back to the frontend with an authorization code.
3. The frontend sends POST /auth/google with the authorization code and redirect URI.
4. The GoogleAuthClient exchanges the code for an access token by calling Google's token endpoint.
5. The GoogleAuthClient uses the access token to fetch the user's profile from Google's userinfo endpoint.
6. The AuthService checks whether a user with the returned Google ID already exists. If so, it logs them in. If not, it creates a new user account with auth_provider = 'google' and email_verified = TRUE (Google has already verified the email).
7. The service generates an access/refresh token pair and returns it as in the local login flow.

5.9.5. Password Hashing

Passwords are hashed using Argon2id (Biryukov, Dinu and Khovratovich, 2016), the winner of the 2015 Password Hashing Competition and the algorithm recommended by OWASP (OWASP Foundation, 2024b). The ArgonPasswordHasher uses libsodium's crypto_pwhash_str() function with MODERATE parameters (3 iterations, 256 MB memory). Argon2id combines the resistance to side-channel attacks of Argon2i with the resistance to GPU cracking of Argon2d.

Figure 7 illustrates the complete login flow.

Sequence diagram for login. Client → Server: POST /auth/login {email, password}. Server: find user by email → verify password hash (Argon2id) → generate access_token (JWT, 15min) + refresh_token (UUID, 7d) → hash refresh_token (SHA-256) → store in refresh_tokens table → return {access_token, csrf_token} + Set-Cookie: refresh_token=..., Set-Cookie: csrf_token=...

Figure 7: Login sequence showing token generation and cookie setting.

5.10. Middleware Pipeline Design

Every inbound HTTP request passes through a pipeline of Drogon filters before reaching the controller. Filters are applied in the order they are listed in the `ADD_METHOD_TO` macro for each route. The four middleware filters form a chain: `CorrelationIdFilter`, then `RateLimitFilter` (on auth routes), then `JwtAuthFilter` (on protected routes), then `CsrfFilter` (on state-changing protected routes). Figure 8 illustrates this.

Middleware filter chain diagram. HTTP Request → CorrelationIdFilter (generates UUID, creates scoped logger, attaches to request attributes) → RateLimitFilter (sliding window 10 req/min/IP, rejects with 429) → JwtAuthFilter (extracts Bearer token, verifies JWT, injects user_id) → CsrfFilter (compares cookie vs header, constant-time) → Controller.

Figure 8: HTTP middleware filter chain.

5.10.1. CorrelationIdFilter

The `CorrelationIdFilter` runs on every route. It generates a UUID v4 correlation ID, creates a request-scoped spdlog logger with the correlation ID embedded in its format pattern, and attaches both the correlation ID string and the logger instance to the request's attribute map. All subsequent code — other filters, controllers, services, repositories — retrieves the logger from the request attributes and uses it for logging. This ensures that every log line produced during a request carries the same correlation ID, enabling end-to-end tracing through aggregated logs.

5.10.2. RateLimitFilter

The `RateLimitFilter` implements a sliding window rate limiter. It maintains an in-memory `std::unordered_map<std::string, std::deque<time_point>>` keyed by client IP address, protected by a `std::mutex`. For each request:

1. Retrieve the client IP from the request's peer address.
2. Lock the mutex.
3. Remove all timestamps older than the window (1 minute) from the deque.
4. If the deque size equals or exceeds `max_requests` (10), reject the request with a 429 Too Many Requests response.
5. Otherwise, push the current timestamp onto the deque and allow the request to proceed.

The in-memory approach is appropriate because the backend runs as a single process with multiple threads (Drogon's thread pool). In a multi-instance deployment, a distributed rate limiter (e.g. Redis-backed) would be needed. The rate limiter is applied only to authentication endpoints (`/auth/*`), which are the primary targets for brute-force attacks.

5.10.3. JwtAuthFilter

The JwtAuthFilter runs on all routes that require authentication (equipment, observations, profile, light curve comparison). It:

1. Extracts the Authorization header.
2. Validates that the header begins with "Bearer ".
3. Passes the token string to `ITokenService::verify_access_token()`, which verifies the JWT signature (HS256), checks the expiry, and validates that the type claim is "access".
4. If verification succeeds, injects the `user_id` claim into the request's attribute map.
5. If verification fails (missing header, invalid format, expired, tampered), returns a 401 response.

5.10.4. CsrfFilter

The CsrfFilter runs on state-changing routes (POST, PUT, DELETE) that are behind the JwtAuthFilter. It:

1. Skips validation for safe methods (GET, HEAD, OPTIONS).
2. Reads the `csrf_token` cookie and the X-CSRF-Token header.
3. If either is missing, returns 403 with "CSRF token is missing".
4. Compares the cookie and header values using `sodium_memcmp()` for constant-time comparison. If they differ, returns 403 with "CSRF token is invalid".
5. If they match, allows the request to proceed.

The constant-time comparison prevents an attacker from inferring the correct CSRF token one byte at a time via timing analysis (Bernstein, 2012).

5.11. Frontend Architecture Design

The frontend is built with Next.js (Vercel, 2024) using the App Router and TypeScript. It serves as the primary user interface for target search, light curve visualisation, equipment management, observation session management, and image upload.

5.11.1. Directory Structure

```
frontend/
+-- app/
|   +-- (auth)/
|   |   +-- login/           Login page
|   |   +-- register/       Registration page
|   |   +-- verify-email/    Email verification page
|   +-- (dashboard)/
|   |   +-- targets/
|   |   |   +-- page.tsx      Target search page
|   |   |   +-- [id]/
|   |   |       +-- page.tsx  Target detail + light curve
|   |   +-- observations/
|   |   |   +-- page.tsx      Session list
|   |   |   +-- [id]/
```

```

|   |   |      +-- page.tsx      Session detail + image upload
|   |   +-- equipment/
|   |      +-- page.tsx      Equipment management
|   +-- layout.tsx      Root layout with auth provider
+-- components/
|   +-- charts/
|   |   +-- LightCurveChart.tsx  Plotly.js light curve viewer
|   +-- ui/      Shared UI components
+-- lib/
|   +-- api.ts      API client with 401 retry
|   +-- auth.ts     Auth context and hooks
+-- types/      TypeScript type definitions

```

5.11.2. API Client with Automatic Token Refresh

The API client module (`lib/api.ts`) wraps `fetch()` with authentication handling. On every request to a protected endpoint, it attaches the access token (stored in a React context / in-memory variable) as a Bearer header and the CSRF token (read from the `csrf_token` cookie) as an X-CSRF-Token header. If the server returns 401 (access token expired), the client automatically sends a refresh request (`POST /auth/refresh`), receives a new access token, and retries the original request. If the refresh also fails (refresh token expired or revoked), the client redirects to the login page. This retry logic is transparent to calling components.

5.11.3. Light Curve Viewer

The light curve viewer is the central visualisation component. It uses Plotly.js (Plotly Technologies Inc., 2024) with WebGL rendering to handle datasets of up to 50,000 data points with smooth zoom and pan interactions. The chart displays:

- **X-axis:** BTJD (Barycentric TESS Julian Date). Tick labels are formatted to show the fractional day.
- **Y-axis:** Normalised flux (PDCSAP flux divided by the median PDCSAP flux), centred near 1.0. Normalisation enables visual comparison between different observation sectors and between TESS and ground-based data.
- **Error bars:** Vertical error bars derived from `PDCSAP_FLUX_ERR`, also normalised.
- **Quality filter toggle:** A checkbox that hides data points with non-zero quality flags. Enabled by default.
- **Data series:** TESS PDCSAP flux as the primary scatter plot. When viewing a comparison, user observation data is overlaid as a second series with distinct styling.

Plotly.js was chosen over D3.js (Bostock, Ogievetsky and Heer, 2011) because Plotly provides built-in WebGL scatter plot support (via `scattergl` trace type), automatic zoom/pan handling, and hover tooltips without requiring manual DOM manipulation. D3 would offer more customisation but at significantly higher implementation cost for the same visualisation quality.

5.11.4. Server-Sent Events for Ingestion Progress

The FITS download and parse stage (Stage 4 of the pipeline) can take several seconds per observation. To provide real-time feedback, the frontend establishes a Server-Sent Events (SSE) connection (W3C, 2015) during the ingestion process. The server sends events with fields like stage, progress, and message that the frontend renders as a progress indicator. SSE was chosen over WebSocket because the communication is unidirectional (server to client only) and SSE has simpler semantics: automatic reconnection, event typing, and native browser support via EventSource.

5.12. Design Decisions and Trade-offs

5.12.1. Why C++ over Python, Go, or Rust

Python is the dominant language in the astronomy data ecosystem (Lightcurve (Lightcurve Collaboration *et al.*, 2018), Astropy, etc.), and would have provided the easiest integration with existing libraries. However, this project is a data science dissertation with emphasis on system design and data engineering, not on reusing high-level astronomy libraries. C++ was chosen for three reasons:

1. **Performance:** C++ enables zero-cost abstractions, predictable memory layout, and direct control over allocation patterns (Stroustrup, 2013). For a backend that parses multi-megabyte FITS binary data and serves tens of thousands of light curve data points per request, this control matters. The FITS parser operates on raw byte arrays; the bulk insert constructs parameterised SQL strings in a tight loop; the JSON serialisation for large responses uses `json_agg` to avoid intermediate object construction.
2. **Systems-level learning:** Building a production-grade HTTP backend in C++ exercises skills in memory management (RAII, smart pointers), concurrency (mutex-protected shared state), binary format parsing (CFITSIO C API), and ABI boundary management (C library interop) that higher-level languages abstract away. These skills are the subject of examination in a data science programme that values understanding the full stack.
3. **Modern C++ expressiveness:** C++23 features — `std::expected` for error handling, designated initialisers for struct construction, `std::optional` for nullable fields, structured bindings for tuple unpacking, `std::string::ends_with` for string matching — provide expressiveness comparable to Go or Rust without sacrificing performance (cppreference.com, 2024).

Go was considered but rejected due to its limited type system (no generics at the time of project inception, no sum types). Rust was considered but rejected due to its steeper learning curve and smaller web framework ecosystem.

5.12.2. Why Drogon over Other C++ Frameworks

Drogon (An, 2024) was chosen over alternative C++ web frameworks (Crow, Pistache, cpp-httplib, Oat++) for four reasons. First, Drogon includes a built-in ORM with PostgreSQL support, eliminating the need for a separate database library. Second, it provides a filter

(middleware) system that maps naturally to the correlation ID, rate limiting, JWT, and CSRF cross-cutting concerns. Third, it is actively maintained and widely used, with reliable documentation. Fourth, it includes a synchronous HTTP client (`HttpClient::sendRequest`) that simplifies the MAST API communication (no callback chains or futures).

5.12.3. Why PostgreSQL B-tree Indexes over TimescaleDB Hypertables

As discussed in Section 5.3.5, the light curve data volume does not justify the additional operational complexity of TimescaleDB. The composite B-tree index on `(tess_observation_id, time)` provides the same query performance for the primary access pattern (retrieve all points for one observation, ordered by time). TimescaleDB's advantages — chunk-level compression, automatic partitioning, chunk-level retention policies, and continuous aggregates — are designed for write-heavy, high-cardinality time-series workloads (Timescale, Inc., 2024). Nyx's workload is write-once-read-many: light curves are bulk-inserted once and then read repeatedly. The standard PostgreSQL B-tree index handles this pattern efficiently (Winand, 2012).

5.12.4. Why Synchronous MAST Requests

The MAST API communication uses Drogon's synchronous HTTP client (`sendRequest` with a timeout). An asynchronous approach (using `sendRequest` with a callback, or using coroutines) would avoid blocking the Drogon event loop thread during the multi-second MAST API calls. The synchronous approach was chosen for simplicity: the ingestion pipeline is triggered by explicit user action (not background processing), the number of concurrent MAST requests is limited (one per user interaction), and Drogon runs multiple event loop threads so a single blocked thread does not prevent other requests from being served. If the platform needed to ingest data for hundreds of targets concurrently, the pipeline would need to be made asynchronous or offloaded to a background worker.

5.12.5. Why Form-Encoded POST to the MAST API

The MAST Portal API's `/api/v0/invoke` endpoint requires that the JSON request payload be URL-encoded and sent as a form parameter named `request` with content type `application/x-www-form-urlencoded` (Space Telescope Science Institute, 2024). This is not a design choice made by Nyx — it is a constraint imposed by the MAST API. The `MastClient` implementation accordingly constructs the form body as `"request=" + urlEncodeComponent(json_string)`.

5.12.6. Why `std::expected` over Exceptions

The codebase uses `std::expected<T, AppError>` (aliased as `Result<T>` (cppreference.com, 2024)) for all recoverable errors in application code, rather than C++ exceptions. This choice has three motivations. First, error paths are visible in the function signature — a caller cannot accidentally ignore an error because `std::expected` must be explicitly checked. Second, the performance characteristics are predictable: `std::expected` is a stack-allocated discriminated union with no heap allocation or stack unwinding. Third, the pattern aligns

with the functional error handling style used in Rust and modern C++, where errors are values rather than control flow interrupts.

Exceptions are still used at infrastructure boundaries where third-party libraries throw them (Drogon ORM's `DrogonDbException`, `nlohmann/json`'s `json::exception`, CFITSIO's error codes). These are caught at the boundary and converted to `AppError` values. No exception propagates out of the infrastructure layer into the application layer.

6. Implementation

This chapter presents the implementation of every major subsystem in the Nyx platform. Each section walks through the real code, explains the design rationale behind non-obvious decisions, and links back to the architectural choices described in Section 5. The chapter is organised bottom-up: foundational infrastructure first (build system, error handling), then the data ingestion pipeline (MAST client, FITS parser, bulk insert), then authentication and security, then the middleware pipeline, then the database access layer and response formatting, and finally the frontend application.

6.1. Build System and Dependencies

The backend uses CMake 3.20+ as the build system and `vcpkg` as the C++ package manager. The `vcpkg.json` manifest declares 12 dependencies:

```
{
  "name": "nyx-backend",
  "version": "0.1.0",
  "dependencies": [
    { "name": "drogon", "features": ["postgres"] },
    "spdlog", "nlohmann-json", "simdjson",
    "jwt-cpp", "libsodium", "json-schema-validator",
    "gtest", "cfitsio", "exiv2", "libraw", "curl"
  ]
}
```

Drogon (An, 2024) provides the HTTP server, routing, and ORM layer; the `postgres` feature enables the PostgreSQL client driver. `nlohmann-json` handles JSON serialisation for request/response bodies and API payloads, while `simdjson` is available for high-throughput parsing of large NASA API responses. `spdlog` provides structured logging with nanosecond timestamps. `jwt-cpp` handles JWT creation and verification. `libsodium` supplies Argon2id password hashing, SHA-256 token hashing, CSRF constant-time comparison, and cryptographic random number generation. `cfitsio` is the reference C library for reading FITS files (Pence *et al.*, 2010). `exiv2` extracts EXIF metadata from observation images. `libraw` decodes DNG raw images from the telescope camera. `curl` is used by the SMTP email sender for sending verification emails over TLS.

The `CMakeLists.txt` targets C++23 and enforces strict compiler diagnostics:

```

cmake_minimum_required(VERSION 3.20)
project(nyx-backend VERSION 0.1.0 LANGUAGES CXX)

set(CMAKE_CXX_STANDARD 23)
set(CMAKE_CXX_STANDARD_REQUIRED ON)
set(CMAKE_CXX_EXTENSIONS OFF)

target_compile_options(${PROJECT_NAME} PRIVATE
    -Wall -Wextra -Wpedantic -Werror
    -Wno-unused-parameter
)

```

The `-Werror` flag promotes all warnings to errors, ensuring that the codebase compiles warning-free. `-Wno-unused-parameter` is the only suppression, needed because Drogon's filter callback signatures often include parameters that are unused in specific filter implementations.

Database migrations are managed by `goose`. The project includes 18 migration files covering user authentication (`create_users`, `create_refresh_tokens`, `add_email_verified_to_users`, `create_verification_tokens`, `add_oauth_fields_to_users`), astronomical data (`create_targets`, `create_tess_observations`, `create_light_curve_points`), equipment (`create_telescopes`, `create_cameras`, `create_mounts`, `create_filters`), observation sessions (`create_observation_sessions`, `add_equipment_fks_to_sessions`, `add_photometry_to_images`), and location data (`create_observing_locations`, `add_unique_location_name_per_user`). Migrations are created via `goose -dir backend/migrations create <name> sql` and applied with `goose -dir backend/migrations up`.

The application entry point in `main.cpp` initialises the logger, configures the database connection pool, and starts the Drogon HTTP server:

```

auto main() -> int {
    try {
        auto config = Nyx::Infrastructure::Config::EnvironmentConfig();
        Nyx::Core::Logger::initialize(config.log_level());

        spdlog::info("Starting Nyx backend v0.1.0");
        spdlog::info("Configuring server on port {} with {} threads",
            config.server_port(), config.server_threads());

        Nyx::Infrastructure::Database::DatabaseManager::initialize(config);

        drogon::app()
            .setLogLevel(trantor::Logger::kFatal)
            .addListener("0.0.0.0", config.server_port())
            .setThreadNum(config.server_threads())
            .registerBeginningAdvice([] {
                spdlog::info("Nyx backend is running");
            })
            .run();
    }
}

```

```

    } catch (const std::exception& exception) {
        spdlog::critical("Fatal error during startup: {}", exception.what());
        return 1;
    }
    return 0;
}

```

Drogon's internal logging is silenced (kFatal) because all application logging goes through spdlog. Controller registration is handled declaratively via macros in each controller's header file; Drogon discovers them at compile time through its code generation system.

6.2. Error Handling with `std::expected`

Every fallible operation in Nyx returns `Nyx::Core::Result<T>`, a type alias for `std::expected<T, AppError>` (cppreference.com, 2024):

```

template<typename T>
using Result = std::expected<T, AppError>;

```

The `AppError` struct carries a machine-readable `ErrorCode` enum, a human-readable message string, and an optional vector of field-level validation errors:

```

enum class ErrorCode {
    ValidationError,          // 400
    InvalidJson,             // 400
    AuthenticationRequired,   // 401
    InvalidToken,            // 401
    TokenExpired,            // 401
    PermissionDenied,        // 403
    EmailNotVerified,        // 403
    ResourceNotFound,        // 404
    Conflict,                // 409
    RateLimitExceeded,       // 429
    InternalError,           // 500
    DatabaseError,           // 500
    ExternalServiceError,    // 500
};

```

Each error code maps to an HTTP status code via `http_status_code()` and to a string representation via `error_code_string()`. The mapping is implemented as a switch over the enum:

```

[[nodiscard]] auto http_status_code() const -> int {
    switch (code) {
        case ErrorCode::ValidationError:
        case ErrorCode::InvalidJson:
            return 400;
        case ErrorCode::AuthenticationRequired:
        case ErrorCode::InvalidToken:
        case ErrorCode::TokenExpired:
            return 401;
    }
}

```

```

        case ErrorCode::PermissionDenied:
        case ErrorCode::EmailNotVerified:
            return 403;
        case ErrorCode::ResourceNotFound:
            return 404;
        case ErrorCode::Conflict:
            return 409;
        case ErrorCode::RateLimitExceeded:
            return 429;
        case ErrorCode::InternalServerError:
        case ErrorCode::DatabaseError:
        case ErrorCode::ExternalServiceError:
            return 500;
    }
    return 500;
}

```

AppError provides static factory methods for common error types, eliminating the need for callers to construct the full struct:

```

static auto validation(
    std::string message,
    std::vector<FieldError> details = {}
) -> AppError {
    return AppError{ErrorCode::ValidationError,
        std::move(message), std::move(details)};
}

static auto not_found(std::string message) -> AppError {
    return AppError{ErrorCode::ResourceNotFound,
        std::move(message), {}};
}

static auto internal(std::string message) -> AppError {
    return AppError{ErrorCode::InternalServerError,
        std::move(message), {}};
}

```

This approach replaces exceptions with explicit error propagation. Callers check `result.has_value()` and access `result.error()` on failure. The pattern is consistent across all three layers of the architecture described in Section 5.1: repositories return `Result<T>`, services return `Result<T>`, and controllers map errors to HTTP responses via `ResponseHelper::error()`. Because `std::expected` is a value type, there is no heap allocation for the error path, and the compiler can optimise the success path as a direct return.

The consistency of this pattern is demonstrated by a typical service method. Every operation that can fail returns a `Result`, and the caller checks each one before proceeding:

```

auto obs_result =
    this->tess_observation_repository->find_by_id(observation_id);

```

```

if (!obs_result.has_value()) {
    return std::unexpected(obs_result.error());
}
if (!obs_result->has_value()) {
    return std::unexpected(
        Nyx::Core::AppError::not_found("TESS observation not found")
    );
}
auto observation = obs_result->value();

```

This two-level unwrapping (first checking for database errors, then for “not found”) is a deliberate design choice. The repository returns `Result<std::optional<T>>` rather than using the error channel for “not found”, because absence is a normal condition (not an error), while a database timeout or connection failure is genuinely exceptional.

6.3. MAST API Client Implementation

The `MastClient` implements the `IMastClient` interface defined in the application layer, as described in Section 5.1. All MAST API calls go through a single base method, `invoke_mast_service`, which handles HTTP transport, error detection, and response extraction.

6.3.1. Base Method: `invoke_mast_service`

Every MAST API call (Space Telescope Science Institute, 2024) follows the same protocol: a form-encoded POST to `https://mast.stsci.edu/api/v0/invoke` with a request parameter containing a JSON payload. The `invoke_mast_service` method encapsulates this:

```

auto MastClient::invoke_mast_service(
    const std::string& request_json
) -> Nyx::Core::Result<std::string> {
    try {
        auto client = drogon::HttpClient::newHttpClient(
            "https://mast.stsci.edu"
        );
        client->setUserAgent("Nyx/1.0");

        auto path = this->base_url + "/invoke";
        auto request = drogon::HttpRequest::newHttpRequest();
        request->setMethod(drogon::Post);
        request->setPath(path);
        request->setContentTypeCode(drogon::CT_APPLICATION_X_FORM);
        auto encoded_body = "request="
            + drogon::utils::urlEncodeComponent(request_json);
        request->setBody(encoded_body);

        spdlog::debug("MAST API request: POST {}", path);
        auto [result, response] = client->sendRequest(request, 60.0);

        if (result != drogon::ReqResult::Ok) {

```

```

        spdlog::error("MAST API request failed: network error");
        return std::unexpected(Nyx::Core::AppError{
            Nyx::Core::ErrorCode::ExternalServiceError,
            "MAST API request failed", {}
        });
    }

    if (response->getStatusCode() != drogon::k200OK) {
        spdlog::error("MAST API returned status {}",
            static_cast<int>(response->getStatusCode()));
        return std::unexpected(Nyx::Core::AppError{
            Nyx::Core::ErrorCode::ExternalServiceError,
            "MAST API returned non-200 status", {}
        });
    }

    return std::string(response->body());
} catch (const std::exception& exception) {
    spdlog::error("MAST API exception: {}", exception.what());
    return std::unexpected(Nyx::Core::AppError{
        Nyx::Core::ErrorCode::ExternalServiceError,
        "MAST API request failed", {}
    });
}
}

```

The JSON payload is URL-encoded and sent as `application/x-www-form-urlencoded`, which is the encoding that the MAST Portal API expects. The 60-second timeout accommodates the occasionally slow MAST responses for large cone searches. Drogon's `sendRequest` returns a structured result that distinguishes network errors (`ReqResult::Ok` vs other values) from HTTP-level errors (non-200 status codes), so both are checked.

6.3.2. Name Resolution

Target name resolution uses the `Mast.Name.Lookup` service. Given a user-supplied target name (e.g. "Pi Mensae", "HAT-P-7", "TIC 261136679"), MAST returns the canonical name, object type, right ascension, and declination:

```

auto request_payload = nlohmann::json{
    {"service", "Mast.Name.Lookup"},
    {"params", {{{"input", name}, {"format", "json"}}}}
};

auto body_result = this->invoke_mast_service(request_payload.dump());
if (!body_result.has_value()) {
    return std::unexpected(body_result.error());
}

auto response_json = nlohmann::json::parse(body_result.value());
auto resolved = response_json.value("resolvedCoordinate",
    nlohmann::json::array())

```

```

);

if (resolved.empty()) {
    return std::unexpected(
        Nyx::Core::AppError::validation("Target could not be resolved")
    );
}

auto first = resolved[0];
auto target = Nyx::Application::Target::ResolvedTarget{
    .canonical_name = first.value("canonicalName", ""),
    .target_type = first.contains("objectType")
        ? std::optional<std::string>(first["objectType"].get<std::string>())
        : std::nullopt,
    .right_ascension = first.contains("ra")
        ? std::optional<double>(first["ra"].get<double>())
        : std::nullopt,
    .declination = first.contains("decl")
        ? std::optional<double>(first["decl"].get<double>())
        : std::nullopt,
};

```

The resolvedCoordinate array may contain multiple matches; only the first is used. Optional fields (objectType, ra, decl) are wrapped in std::optional because MAST does not guarantee their presence for all object types.

6.3.3. TESS Observation Search and Columnar Response Parsing

The search_tess_timeseries method queries Mast.Caom.Filtered.Position with two filters: obs_collection = "TESS" and dataproduct_type = "timeseries". The search uses a cone search centred on the resolved coordinates:

```

auto position = std::to_string(ra) + ", "
    + std::to_string(dec) + ", " + std::to_string(radius);

auto request_payload = nlohmann::json{
    {"service", "Mast.Caom.Filtered.Position"},
    {"params", {
        {"columns", "obsid,t_exptime,t_min,t_max"},
        {"filters", nlohmann::json::array({
            {"paramName", "obs_collection"}, {"values", {"TESS"}}},
            {"paramName", "dataproduct_type"}, {"values", {"timeseries"}}
        })},
        {"position", position},
        {"format", "json"}
    }}
};

```

MAST returns data in a columnar format rather than the row-oriented JSON most APIs use. The response contains Tables[0].Fields (column definitions) and Tables[0].Rows (data

rows). Each row is a positional array, not a named object. The client must first discover column indices by scanning Fields, then access row elements by index:

```
auto table = tables[0];
auto fields = table.value("Fields", nlohmann::json::array());
auto rows = table.value("Rows", nlohmann::json::array());

auto obsid_index = -1;
auto exptime_index = -1;
auto tmin_index = -1;
auto tmax_index = -1;

for (auto i = 0; i < static_cast<int>(fields.size()); ++i) {
    auto field_name = fields[i].value("name", "");
    if (field_name == "obsid") obsid_index = i;
    else if (field_name == "t_exptime") exptime_index = i;
    else if (field_name == "t_min") tmin_index = i;
    else if (field_name == "t_max") tmax_index = i;
}
```

This index-based reconstruction is necessary because MAST does not guarantee column ordering. The same pattern is repeated for every columnar MAST endpoint. If any required column is missing and there are data rows present, the method returns an error; if rows are empty, it returns an empty vector (missing columns on an empty result set is not an error because the server may omit column metadata when there are no results).

Row extraction handles type polymorphism in the obsid field: MAST sometimes returns it as a string, sometimes as an integer:

```
for (const auto& row : rows) {
    auto obsid_value = row[obsid_index];
    auto obsid = obsid_value.is_string()
        ? obsid_value.get<std::string>()
        : std::to_string(obsid_value.get<int64_t>());

    auto cadence = static_cast<int>(
        exptime_value.get<double>()
    );

    observations.push_back(
        Nyx::Application::Target::MastObservation{
            .obsid = obsid,
            .cadence_seconds = cadence,
            .start_time = tmin_value.get<double>(),
            .end_time = tmax_value.get<double>(),
        }
    );
}
```

6.3.4. Product Discovery

The `get_data_products` method queries `Mast.Caom.Products` for a given observation ID. It uses the same columnar parsing approach to extract the `dataURI`, `description`, `productType`, and `productFilename` fields:

```
auto request_payload = nlohmann::json{
    {"service", "Mast.Caom.Products"},
    {"params", {{{"obsid", obsid}, {"format", "json"}}}}
};
```

The service layer filters the results to find the TESS light curve FITS file, identified by three criteria: the description is "Light curves", the product type is "SCIENCE", and the filename ends with `_lc.fits`:

```
for (const auto& product : products_result.value()) {
    if (product.description == "Light curves"
        && product.product_type == "SCIENCE"
        && product.filename.ends_with("_lc.fits")) {
        lc_data_uri = product.data_uri;
        break;
    }
}
```

This filter reliably identifies the Pre-search Data Conditioning Simple Aperture Photometry (PDCSAP) light curve files produced by the TESS Science Processing Operations Center (SPOC) pipeline (Jenkins *et al.*, 2016).

6.3.5. FITS File Download with Redirect Following

The `download_fits` method sends an HTTP GET to `https://mast.stsci.edu/api/v0.1/Download/file?uri=<data_uri>`. MAST's download endpoint frequently responds with an HTTP redirect (301, 302, or 307) to a CDN URL rather than serving the file directly. Drogon's HTTP client does not follow redirects automatically, so the `MastClient` implements redirect handling manually:

```
auto MastClient::download_fits(const std::string& data_uri)
-> Nyx::Core::Result<std::string> {
    auto client = drogon::HttpClient::newHttpClient(
        "https://mast.stsci.edu"
    );
    client->setUserAgent("Nyx/1.0");
    auto full_path = std::string{"/api/v0.1/Download/file"}
        + "?uri=" + data_uri;

    // ... create and send request with 120s timeout ...

    auto status_code = response->getStatusCode();
    if (status_code == drogon::k307TemporaryRedirect
        || status_code == drogon::k302Found
        || status_code == drogon::k301MovedPermanently) {
```

```

    auto location = std::string{response->getHeader("Location")};

    if (location.empty()) {
        return std::unexpected(Nyx::Core::AppError{
            Nyx::Core::ErrorCode::ExternalServiceError,
            "MAST redirect missing Location header", {}
        });
    }

    auto scheme_end = location.find("://");
    auto path_start = location.find('/', scheme_end + 3);
    auto redirect_host = (path_start != std::string::npos)
        ? location.substr(0, path_start) : location;
    auto redirect_path = (path_start != std::string::npos)
        ? location.substr(path_start) : "/";

    auto redirect_client =
        drogon::HttpClient::newHttpClient(redirect_host);
    redirect_client->setUserAgent("Nyx/1.0");
    // ... create and send redirect request ...

    auto body = std::string(redirect_response->body());
    spdlog::info("Downloaded FITS file: {} bytes", body.size());
    return body;
}

// Direct response (no redirect)
auto body = std::string(response->body());
return body;
}

```

The redirect URL is parsed to extract the host (scheme + authority) and path components. A new HTTP client is created for the redirect host because Drogon clients are bound to a single host at construction time. The 120-second timeout on both the initial and redirect requests accommodates large FITS files (typically 5–30 MB for TESS light curves).

6.4. FITS Parser Implementation

The `FitsParser` implements the `IFitsParser` interface. It uses the CFITSIO library (Pence *et al.*, 2010) to read TESS light curve FITS files, as described in the design in Section 5.6.

6.4.1. Temporary File Approach and RAII Cleanup

CFITSIO operates on file descriptors and cannot read from in-memory buffers. Since the FITS data arrives as a `std::string` from the download step, the parser must write it to a temporary file first:

```

auto temp_template = std::string{"/tmp/nyx_fits_XXXXXX"};
auto fd = mkstemp(temp_template.data());
if (fd < 0) {
    spdlog::error("Failed to create temp file for FITS data");
}

```

```

    return std::unexpected(
        Nyx::Core::AppError::internal("Failed to create temp file")
    );
}

auto guard = FitsFileGuard{temp_template};

auto bytes_written = write(fd, fits_data.data(), fits_data.size());
close(fd);

```

The FitsFileGuard is a RAII class that deletes the temporary file when the function exits, regardless of the exit path:

```

class FitsFileGuard {
public:
    explicit FitsFileGuard(const std::string& path) : path(path) {}
    ~FitsFileGuard() {
        if (!this->path.empty()) {
            std::remove(this->path.c_str());
        }
    }
    FitsFileGuard(const FitsFileGuard&) = delete;
    auto operator=(const FitsFileGuard&) -> FitsFileGuard& = delete;
private:
    std::string path;
};

```

This ensures no temporary files are leaked, even when the parser returns early due to a CFITSIO error.

6.4.2. HDU Navigation and Column Discovery

TESS light curve FITS files follow the standard structure: HDU 1 contains the primary header, and HDU 2 contains the binary table extension with the time-series data (Pence *et al.*, 2010). The parser moves to HDU 2 and reads the row count:

```

fitsfile* fptr = nullptr;
auto status = 0;
fits_open_file(&fptr, temp_template.c_str(), READONLY, &status);

fits_movabs_hdu(fptr, 2, nullptr, &status);
if (status != 0) {
    char error_text[FLEN_STATUS];
    fits_get_errstatus(status, error_text);
    spdlog::error("Failed to move to HDU 2: {}", error_text);
    fits_close_file(fptr, &status);
    return std::unexpected(Nyx::Core::AppError{
        Nyx::Core::ErrorCode::ExternalServiceError,
        "FITS file missing binary table extension", {}
    });
}

```

```
long num_rows = 0;
fits_get_num_rows(fptr, &num_rows, &status);
```

Column indices are discovered by name using `fits_get_colnum` with case-insensitive matching. The `TIME` column is required; all other columns (`PDCSAP_FLUX`, `PDCSAP_FLUX_ERR`, `SAP_FLUX`, `QUALITY`) are optional. If a column is missing, its index is set to zero and the corresponding values in the output are set to `std::nullopt`:

```
auto time_col = 0;
auto pdcsap_col = 0;
// ...

fits_get_colnum(fptr, CASEINSEN,
    const_cast<char*>("TIME"), &time_col, &status);
if (status != 0) {
    spdlog::error("FITS file missing TIME column");
    fits_close_file(fptr, &status);
    return std::unexpected(Nyx::Core::AppError{
        Nyx::Core::ErrorCode::ExternalServiceError,
        "FITS file missing TIME column", {}
    });
}

status = 0;
fits_get_colnum(fptr, CASEINSEN,
    const_cast<char*>("PDCSAP_FLUX"), &pdcsap_col, &status);
if (status != 0) {
    spdlog::warn("FITS file missing PDCSAP_FLUX column");
    pdcsap_col = 0;
    status = 0;
}
```

The `const_cast<char*>` is necessary because CFITSIO's C API takes a non-const `char*` for the column name parameter, despite not modifying it. The status variable is reset to zero between column lookups because CFITSIO accumulates errors — a non-zero status from a missing optional column would cause all subsequent calls to fail.

6.4.3. Bulk Column Reading into Contiguous Arrays

Rather than reading the FITS table row by row, the parser reads entire columns at once into pre-allocated contiguous `std::vector` arrays. This is both simpler and significantly faster, as CFITSIO can read the entire column in a single I/O operation:

```
auto time_values = std::vector<double>(num_rows);
auto pdcsap_values = std::vector<float>(num_rows);
auto pdcsap_err_values = std::vector<float>(num_rows);
auto sap_values = std::vector<float>(num_rows);
auto quality_values = std::vector<int>(num_rows);

auto any_null = 0;
```

```
fits_read_col(fp_ptr, TDOUBLE, time_col, 1, 1, num_rows,
    nullptr, time_values.data(), &any_null, &status);

if (pdcsap_col > 0) {
    auto nan_val = std::numeric_limits<float>::quiet_NaN();
    fits_read_col(fp_ptr, TFLOAT, pdcsap_col, 1, 1, num_rows,
        &nan_val, pdcsap_values.data(), &any_null, &status);
}
```

For nullable float columns, a NaN sentinel value is passed as the `nan_val` parameter. CFITSIO replaces null entries in the FITS table with this sentinel, which the post-processing loop then checks. The QUALITY column uses integer type (TINT) and does not require null handling because TESS always populates this field.

6.4.4. NaN Filtering and Point Construction

The final loop iterates over the arrays, skipping rows where the timestamp is NaN (indicating missing or invalid data), and constructs `LightCurvePoint` structs:

```
auto points = std::vector<Nyx::Domain::LightCurvePoint>{};
points.reserve(num_rows);

for (auto i = long{0}; i < num_rows; ++i) {
    if (std::isnan(time_values[i])) continue;

    auto point = Nyx::Domain::LightCurvePoint{
        .id = 0,
        .tess_observation_id = "",
        .time = time_values[i],
        .pdcsap_flux = (pdcsap_col > 0
            && !std::isnan(pdcsap_values[i]))
            ? std::optional<float>(pdcsap_values[i])
            : std::nullopt,
        .pdcsap_flux_err = (pdcsap_err_col > 0
            && !std::isnan(pdcsap_err_values[i]))
            ? std::optional<float>(pdcsap_err_values[i])
            : std::nullopt,
        .sap_flux = (sap_col > 0
            && !std::isnan(sap_values[i]))
            ? std::optional<float>(sap_values[i])
            : std::nullopt,
        .quality = (quality_col > 0)
            ? quality_values[i] : 0,
    };

    points.push_back(point);
}

spdlog::info("Parsed {} light curve points from FITS ({} rows total)",
    points.size(), num_rows);
return points;
```

The `id` and `tess_observation_id` fields are set to placeholder values (0 and empty string) because they are assigned by the database during bulk insert. A typical TESS single-sector 2-minute cadence observation contains approximately 18,000–20,000 rows; after NaN filtering, roughly 17,000–18,000 valid points remain.

The memory layout of the intermediate arrays (`std::vector<double>`, `std::vector<float>`) is contiguous, which enables efficient cache-line utilisation during the filtering loop. The `reserve(num_rows)` call on the output vector avoids reallocations during the push-back loop.

6.5. Data Ingestion Pipeline Implementation

The `TargetService` orchestrates the four-stage data ingestion pipeline described in Section 5.5. It depends on six interfaces, all injected via constructor:

```
TargetService::TargetService(
    std::shared_ptr<IMastClient> mast_client,
    std::shared_ptr<Nyx::Domain::ITargetRepository> target_repository,
    std::shared_ptr<Nyx::Domain::ITessObservationRepository>
        tess_observation_repository,
    std::shared_ptr<Nyx::Core::IUuidGenerator> uuid_generator,
    std::shared_ptr<Nyx::Domain::ILightCurvePointRepository>
        light_curve_point_repository,
    std::shared_ptr<IFitsParser> fits_parser
)
: mast_client(std::move(mast_client))
, target_repository(std::move(target_repository))
, tess_observation_repository(std::move(tess_observation_repository))
, uuid_generator(std::move(uuid_generator))
, light_curve_point_repository(std::move(light_curve_point_repository))
, fits_parser(std::move(fits_parser)) {}
```

All dependencies are interfaces (pure abstract classes), which means the service can be tested with mock implementations — a property exploited extensively in the test suite, as discussed in Section 5.1.

6.5.1. Stage 1–2: `resolve_target` — Name Resolution and Observation Cataloguing

The `resolve_target` method implements the first two stages of the pipeline. It follows a cache-first strategy: if the target has already been resolved and stored, it returns the cached record with its associated TESS observations rather than querying MAST again:

```
auto resolved = this->mast_client->resolve_target(request.target_name);
if (!resolved.has_value()) {
    return std::unexpected(resolved.error());
}

auto cached = this->target_repository->find_by_canonical_name(
    resolved->canonical_name
);
```

```

if (!cached.has_value()) {
    return std::unexpected(cached.error());
}

if (cached->has_value()) {
    auto existing = cached->value();
    logger->info("Target '{}' already cached as id={}",
        existing.canonical_name, existing.id);

    auto observations = this->build_observation_responses(
        existing.id, logger
    );
    if (!observations.has_value()) {
        return std::unexpected(observations.error());
    }
    return TargetResponse{
        .id = existing.id,
        .canonical_name = existing.canonical_name,
        .target_type = existing.target_type,
        .right_ascension = existing.right_ascension,
        .declination = existing.declination,
        .tess_observations = observations.value(),
    };
}

```

If the target is not cached, a new record is created and the TESS observation search is triggered. The search results are filtered to exclude multi-sector stacked observations (those spanning more than 30 days), which would contain duplicate data from individual sector observations:

```

constexpr auto max_single_sector_days = 30.0;

auto single_sector_obs = std::vector<MastObservation>{};
for (const auto& mast_obs : tess_result.value()) {
    auto span_days = mast_obs.end_time - mast_obs.start_time;
    if (span_days > max_single_sector_days) {
        logger->debug(
            "Skipping multi-sector observation obsid={} (span={:.1f} days)",
            mast_obs.obsid, span_days
        );
        continue;
    }
    single_sector_obs.push_back(mast_obs);
}

```

A TESS sector is approximately 27 days (Ricker *et al.*, 2015), so the 30-day threshold provides a small margin while reliably filtering out multi-sector stacks (which typically span 54+ days).

To ensure idempotent re-ingestion, the method queries the database for already-stored observation IDs and filters them out before the bulk insert:

```

auto existing_result =
    this->tess_observation_repository->find_existing_obsids(obsids);
// ...
auto new_observations = std::vector<Nyx::Domain::TessObservation>{};
for (const auto& mast_obs : single_sector_obs) {
    if (existing_obsids.contains(mast_obs.obsid)) {
        logger->debug("TESS observation obsid={} already exists, skipping",
            mast_obs.obsid);
        continue;
    }
    new_observations.push_back(Nyx::Domain::TessObservation{
        .id = this->uuid_generator->generate(),
        .target_id = created.id,
        .obsid = mast_obs.obsid,
        .cadence_seconds = mast_obs.cadence_seconds,
        .start_time = mast_obs.start_time,
        .end_time = mast_obs.end_time,
        .data_uri = std::nullopt,
    });
}

if (!new_observations.empty()) {
    auto bulk_result =
        this->tess_observation_repository->bulk_create(new_observations);
    // ...
}

```

This `find_existing_obsids` check avoids violating the unique constraint on `obsid` and eliminates redundant database writes when the same target is resolved multiple times.

6.5.2. Stage 3: `discover_products` — FITS Data Product Selection

The `discover_products` method implements stage 3: querying MAST for data products associated with a specific observation and selecting the light curve FITS file. The method is idempotent — if the observation already has a `data_uri`, it returns immediately:

```

if (observation.data_uri.has_value()) {
    logger->info(
        "Observation {} already has data_uri, skipping discovery",
        observation_id
    );
    return TessObservationResponse{ /* ... */ };
}

auto products_result = this->mast_client->get_data_products(
    observation.obsid
);

```

The FITS file selection criteria ("Light curves" + "SCIENCE" + `_lc.fits` suffix) are applied to find the SPOC-produced PDCSAP light curve among potentially dozens of data products per observation.

6.5.3. Stage 4: `fetch_light_curve` — Download, Parse, and Store

The `fetch_light_curve` method implements the final stage. It includes a caching check: if light curve points already exist in the database for this observation, the method returns metadata without re-downloading:

```
auto count_result =
    this->light_curve_point_repository->count_by_observation_id(
        observation_id
    );
if (!count_result.has_value()) {
    return std::unexpected(count_result.error());
}

if (count_result.value() > 0) {
    logger->info(
        "Light curve already fetched for observation_id={} ({} points)",
        observation_id, count_result.value()
    );
    // Return cached metadata (point_count, time_min, time_max)
}
```

If no cached data exists, the method proceeds through download, parse, and bulk insert:

```
auto download_result = this->mast_client->download_fits(
    observation.data_uri.value()
);
// ... error handling ...

auto parse_result = this->fits_parser->parse_light_curve(
    download_result.value()
);
// ... error handling ...

auto& points = parse_result.value();
logger->info("Inserting {} light curve points for observation_id={}",
    points.size(), observation_id);

auto insert_result =
    this->light_curve_point_repository->bulk_create(
        observation_id, points
    );
```

The method returns a `LightCurveMetadataResponse` containing the point count, minimum time, and maximum time — not the full point data, which can be retrieved separately via `get_light_curve`.

6.5.4. Performance Timing in `get_light_curve`

The `get_light_curve` method includes explicit timing instrumentation to monitor database query performance for large result sets:

```

auto db_start = std::chrono::steady_clock::now();

auto points_result =
    this->light_curve_point_repository->find_by_observation_id(
        observation_id, quality_filter
    );

auto db_elapsed =
    std::chrono::duration_cast<std::chrono::milliseconds>(
        std::chrono::steady_clock::now() - db_start
    ).count();
logger->debug("Light curve DB fetch took {}ms ({} points)",
    db_elapsed,
    points_result.has_value() ? points_result->size() : 0);

```

This timing data is logged at the debug level and is used during development to identify slow queries. For a typical 18,000-point light curve, the fetch completes in 10–50ms depending on database load.

6.6. Bulk Insert Optimisation

Inserting 18,000 light curve points one row at a time would require 18,000 round trips to PostgreSQL (The PostgreSQL Global Development Group, 2024). The `PostgresLightCurvePointRepository` instead uses batched multi-row INSERT statements with parameterised placeholders:

```

static constexpr auto BATCH_SIZE = 5000;
static constexpr auto PARAMS_PER_ROW = 6;

auto PostgresLightCurvePointRepository::bulk_create(
    const std::string& observation_id,
    const std::vector<Nyx::Domain::LightCurvePoint>& points
) -> Nyx::Core::Result<int> {
    if (points.empty()) return 0;

    try {
        auto db = drogon::app().getDbClient();
        auto transaction = db->newTransaction();
        auto total_inserted = 0;

        for (auto batch_start = size_t{0};
            batch_start < points.size();
            batch_start += BATCH_SIZE) {
            auto batch_end = std::min(
                batch_start + BATCH_SIZE, points.size()
            );
            auto batch_size = static_cast<int>(batch_end - batch_start);

            auto sql = std::ostringstream{};
            sql << "INSERT INTO light_curve_points "
                << "(tess_observation_id, time, pdcsap_flux, "

```

```

        << "pdcsap_flux_err, sap_flux, quality) VALUES ";

for (auto i = 0; i < batch_size; ++i) {
    if (i > 0) sql << ", ";
    auto offset = i * PARAMS_PER_ROW;
    sql << "(" << (offset + 1)
        << ", " << (offset + 2)
        << ", CAST(NULLIF($" << (offset + 3)
        << ", '') AS REAL)"
        << ", CAST(NULLIF($" << (offset + 4)
        << ", '') AS REAL)"
        << ", CAST(NULLIF($" << (offset + 5)
        << ", '') AS REAL)"
        << ", $" << (offset + 6) << ")";
}

auto query = sql.str();
auto binder = *transaction << query;

for (auto i = batch_start; i < batch_end; ++i) {
    const auto& point = points[i];
    binder << observation_id;
    binder << std::to_string(point.time);
    binder << optional_float_to_string(point.pdcsap_flux);
    binder << optional_float_to_string(point.pdcsap_flux_err);
    binder << optional_float_to_string(point.sap_flux);
    binder << std::to_string(point.quality);
}

binder << drogon::orm::Mode::Blocking;
binder >> [(const drogon::orm::Result&) {}];
binder.exec();

total_inserted += batch_size;
}
return total_inserted;
} catch (const drogon::orm::DrogonDbException& exception) {
    spdlog::error(
        "Database error bulk inserting light curve points: {}",
        exception.base().what()
    );
    return std::unexpected(
        Nyx::Core::AppError::internal("Failed to insert light curve points")
    );
}
}

```

Several design decisions are visible here. First, the batch size of 5,000 was chosen empirically: it stays well within PostgreSQL's parameter limit (65,535) at 30,000 parameters per batch (6 per row times 5,000 rows), while being large enough to amortise the per-statement overhead. Second, nullable float columns use the `CAST(NULLIF($N, '') AS REAL)` pattern:

optional values are serialised as empty strings when absent, and NULLIF converts the empty string to SQL NULL before CAST converts the non-empty string to REAL. This avoids the complexity of Drogon's `std::optional` parameter binding, which does not reliably work with its SQL binder for bulk operations. Third, the entire operation is wrapped in a transaction, ensuring atomicity: either all points are inserted or none are.

6.6.1. Server-Side JSON Aggregation

When the frontend requests light curve data for rendering, the naive approach would be to fetch 18,000 rows from PostgreSQL, map each row to a C++ struct, serialise each struct to JSON, and assemble the JSON array. This involves 18,000 `nlohmann::json` object constructions and a large number of small heap allocations.

The `find_by_observation_id_as_json` method delegates JSON construction entirely to PostgreSQL using `json_agg` and `json_build_object`:

```
auto query = std::string{
    "SELECT COALESCE(json_agg("
    "json_build_object("
    "'time', time, "
    "'pdcsap_flux', pdcsap_flux, "
    "'pdcsap_flux_err', pdcsap_flux_err, "
    "'sap_flux', sap_flux, "
    "'quality', quality"
    ") ORDER BY time ASC), '[]'::json)::text "
    "FROM light_curve_points "
    "WHERE tess_observation_id = $1"
};

if (quality_filter) {
    query += " AND quality = 0";
}

auto result = db->execSqlSync(query, observation_id);
return result[0][0].as<std::string>();
```

PostgreSQL returns a single text value containing the complete JSON array. The C++ layer receives this as a `std::string` and inserts it directly into the response body without parsing or re-serialising it. The controller constructs the response envelope using string concatenation rather than `nlohmann::json` to avoid parsing the large JSON array:

```
auto buf = std::string{};
buf.reserve(result->points_json.size() + 256);

buf += "{\"data\":{\"tess_observation_id\":\"";
buf += result->tess_observation_id;
buf += "\",\"obsid\":\"";
buf += result->obsid;
buf += "\",\"point_count\":\"";
buf += std::to_string(result->point_count);
buf += "\",\"points\":";
```

```

buf += result->points_json;
buf += "},\"meta\":{\"request_id\":\"";
buf += correlation_id;
buf += "\",\"timestamp\":\"";
buf += trantor::Date::now().toFormattedString(false);
buf += "\"}"}";

auto response = drogon::HttpResponse::newHttpResponse();
response->setStatusCode(drogon::k200OK);
response->setContentTypeCode(drogon::CT_APPLICATION_JSON);
response->setBody(std::move(buf));
callback(response);

```

The `reserve` call pre-allocates buffer space based on the JSON string size plus a small overhead for the envelope, avoiding reallocations during concatenation. This approach eliminates all C++ JSON serialisation overhead for light curve data and transfers the serialisation work to PostgreSQL's highly optimised JSON functions.

6.7. Authentication Implementation

The authentication system implements the architecture described in Section 5.9, covering password hashing, JWT token management, refresh token rotation, Google OAuth2 integration, and email verification.

6.7.1. Password Hashing: Argon2id via libsodium

Password hashing uses Argon2id (Biryukov, Dinu and Khovratovich, 2016), accessed through libsodium's high-level `crypto_pwhash_str` API. Argon2id combines the side-channel resistance of Argon2i with the GPU-resistance of Argon2d, making it the recommended choice for password hashing (OWASP Foundation, 2024b):

```

auto ArgonPasswordHasher::hash(
    const std::string& password
) -> Nyx::Core::Result<std::string> {
    char hashed_password[crypto_pwhash_STRBYTES];

    if (crypto_pwhash_str(
        hashed_password,
        password.c_str(),
        password.length(),
        crypto_pwhash_OPSLIMIT_MODERATE,
        crypto_pwhash_MEMLIMIT_MODERATE) != 0) {
        return std::unexpected(
            Nyx::Core::AppError::internal("Password hashing failed")
        );
    }

    return std::string(hashed_password);
}

```

```

auto ArgonPasswordHasher::verify(
    const std::string& password,
    const std::string& hash
) -> bool {
    return crypto_pwhash_str_verify(
        hash.c_str(),
        password.c_str(),
        password.length()
    ) == 0;
}

```

The OPSLIMIT_MODERATE and MEMLIMIT_MODERATE parameters configure Argon2id to use moderate CPU and memory costs, balancing security against server load. The crypto_pwhash_str function produces a self-describing output string that includes the algorithm identifier, salt, parameters, and hash, so no separate salt storage is needed. The crypto_pwhash_str_verify function performs constant-time comparison internally, preventing timing attacks.

The constructor initialises libsodium, which is a required one-time setup:

```

ArgonPasswordHasher::ArgonPasswordHasher() {
    if (sodium_init() < 0) {
        spdlog::critical("Failed to initialize libsodium");
        throw std::runtime_error("Failed to initialize libsodium");
    }
}

```

This is the only place in the codebase where an exception is thrown rather than returning a Result, because libsodium initialisation failure is a fatal startup error — the application cannot function without cryptographic primitives.

6.7.2. JWT Token Generation and Verification

The JwtTokenService generates access/refresh token pairs and verifies them using HS256 (HMAC-SHA256) (Jones, Bradley and Sakimura, 2015). Access tokens carry a 15-minute expiry; refresh tokens carry a 7-day expiry:

```

auto JwtTokenService::generate_token_pair(
    const std::string& user_id,
    const std::string& email,
    const std::string& token_id,
    const std::optional<std::string>& family_id
) -> Nyx::Application::Auth::TokenPair {
    auto now = std::chrono::system_clock::now();
    auto resolved_family_id = family_id.value_or(token_id);

    auto access_token = jwt::create()
        .set_issuer("nyx")
        .set_type("access")
        .set_issued_at(now)
        .set_expires_at(now + std::chrono::seconds(

```

```

        this->config->jwt_access_token_expiry_seconds()
    ))
    .set_payload_claim("sub", jwt::claim(user_id))
    .set_payload_claim("email", jwt::claim(email))
    .sign(jwt::algorithm::hs256{this->config->jwt_secret()});

    auto refresh_token = jwt::create()
        .set_issuer("nyx")
        .set_type("refresh")
        .set_id(token_id)
        .set_issued_at(now)
        .set_expires_at(refresh_expiry)
        .set_payload_claim("sub", jwt::claim(user_id))
        .set_payload_claim("email", jwt::claim(email))
        .set_payload_claim("fid", jwt::claim(resolved_family_id))
        .sign(jwt::algorithm::hs256{this->config->jwt_secret()});

    return Nyx::Application::Auth::TokenPair{
        .access_token = std::move(access_token),
        .refresh_token = std::move(refresh_token),
        .refresh_token_id = token_id,
        .refresh_token_family_id = resolved_family_id,
        .refresh_token_expires_at = expiry_stream.str(),
    };
}

```

The type claim distinguishes access tokens from refresh tokens at the verification stage. The fid (family ID) claim in the refresh token links all tokens in a rotation chain to a common family, enabling family-wide revocation on reuse detection.

Token verification uses the jwt-cpp library's verifier, which checks the signature, issuer, and type:

```

auto JwtTokenService::verify_access_token(
    const std::string& token
) -> Nyx::Core::Result<Nyx::Application::Auth::TokenClaims> {
    try {
        auto decoded_token = jwt::decode(token);
        auto verifier = jwt::verify()
            .allow_algorithm(jwt::algorithm::hs256{this->config->jwt_secret()})
            .with_issuer("nyx")
            .with_type("access");
        verifier.verify(decoded_token);

        return Nyx::Application::Auth::TokenClaims{
            .user_id = decoded_token.get_payload_claim("sub").as_string(),
            .email = decoded_token.get_payload_claim("email").as_string(),
        };
    } catch (const jwt::error::token_verification_exception& exception) {
        return std::unexpected(
            Nyx::Core::AppError::invalid_token("Access token is invalid")
        );
    }
}

```

```

    }
}

```

6.7.3. Token Hashing with SHA-256

Refresh tokens are never stored in plaintext in the database. Instead, a SHA-256 hash is computed via libsodium and stored. This way, a database breach does not directly expose valid refresh tokens (Bernstein, 2012):

```

auto JwtTokenService::hash_token(
    const std::string& token
) -> std::string {
    unsigned char hash[crypto_hash_sha256_BYTES];
    crypto_hash_sha256(
        hash,
        reinterpret_cast<const unsigned char*>(token.c_str()),
        token.size()
    );

    char hex[crypto_hash_sha256_BYTES * 2 + 1];
    sodium_bin2hex(hex, sizeof(hex), hash, crypto_hash_sha256_BYTES);
    return std::string(hex);
}

```

The hash is stored as a lowercase hexadecimal string. When a refresh token is presented for rotation, the same hashing function is applied and the result is used to look up the stored record.

6.7.4. Refresh Token Rotation with Family-Based Reuse Detection

The `refresh_access_token` method in `AuthService` implements the rotation logic described in Section 5.9. When a valid refresh token is presented:

1. The token is verified (signature + expiry).
2. The SHA-256 hash is computed and used to look up the stored record.
3. If the stored record is revoked, the entire token family is revoked and an error is returned.
4. Otherwise, the current token is revoked and a new token pair is issued with the same family ID.

```

auto stored_token = stored_token_result->value();

if (stored_token.is_revoked) {
    logger->warn(
        "Reuse detected for token family_id={}, revoking entire family",
        stored_token.family_id
    );
    auto revoke_result =
        this->refresh_token_repository->revoke_family(
            stored_token.family_id
        );
    return std::unexpected(

```

```

        Nyx::Core::AppError::invalid_token(
            "Refresh token has been revoked"
        )
    );
}

auto revoke_old_result =
    this->refresh_token_repository->revoke(stored_token.id);
// ...

auto new_token_pair =
    this->token_service->generate_token_pair(
        claims.user_id, claims.email,
        new_token_id, stored_token.family_id
    );

```

The reuse detection works as follows (Lodderstedt *et al.*, 2020): if an attacker steals a refresh token and uses it, the legitimate user's next refresh attempt will present a token that has already been revoked. This triggers family-wide revocation, invalidating both the attacker's and the user's tokens. The user must re-authenticate, but the attacker loses access.

6.7.5. Google OAuth2 Integration

The GoogleAuthClient exchanges an authorization code for user information by POSTing to Google's token endpoint (Hardt, 2012):

```

auto GoogleAuthClient::exchange_code(
    const std::string& code,
    const std::string& redirect_uri
) -> Nyx::Core::Result<Nyx::Application::Auth::GoogleUserInfo> {
    // ...
    auto http_client = drogon::HttpClient::newHttpClient(
        "https://oauth2.googleapis.com"
    );

    auto request = drogon::HttpRequest::newHttpRequest();
    request->setMethod(drogon::Post);
    request->setPath("/token");
    request->setContentTypeCode(drogon::CT_APPLICATION_X_FORM);
    request->setBody(
        "code=" + code
        + "&client_id=" + client_id
        + "&client_secret=" + client_secret
        + "&redirect_uri=" + redirect_uri
        + "&grant_type=authorization_code"
    );

    auto [result, response] = http_client->sendRequest(request, 10.0);
    // ... error handling ...

    auto response_body = nlohmann::json::parse(response->body());
}

```

```

auto id_token_str = response_body["id_token"].get<std::string>();
auto decoded_token = jwt::decode(id_token_str);

auto google_id = decoded_token.get_payload_claim("sub").as_string();
auto email = decoded_token.get_payload_claim("email").as_string();
// ...

return Nyx::Application::Auth::GoogleUserInfo{
    .google_id = std::move(google_id),
    .email = std::move(email),
    .email_verified = email_verified,
    .name = std::move(name),
};
}

```

The ID token is decoded without signature verification because it was received directly from Google over HTTPS — verifying the TLS connection is sufficient per the OpenID Connect specification (Sakimura *et al.*, 2014). The sub claim contains the stable Google user ID.

The `AuthService::google_login` method handles three cases for the user lookup:

```

// Case 1: Existing user found by Google ID
auto existing_google_user =
    this->user_repository->find_by_google_id(google_user.google_id);
if (existing_google_user->has_value()) {
    auto user = existing_google_user->value();
    // Issue tokens and return
}

// Case 2: Email conflict with local account
auto existing_email_user =
    this->user_repository->find_by_email(google_user.email);
if (existing_email_user->has_value()) {
    return std::unexpected(Nyx::Core::AppError::conflict(
        "An account with this email already exists. "
        "Please log in with your password."
    ));
}

// Case 3: New user
auto new_user = Nyx::Domain::User{
    .id = this->uuid_generator->generate(),
    .email = google_user.email,
    .password_hash = std::nullopt,
    .display_name = google_user.name,
    .email_verified = true,
    .auth_provider = "google",
    .google_id = google_user.google_id,
};
auto create_result = this->user_repository->create(new_user);

```

Google-authenticated users are created with `email_verified = true` (Google has already verified the email), `password_hash = std::nullopt` (no local password), and `auth_provider = "google"`. The conflict case prevents automatic account linking: if a user registered with email/password and later tries Google login with the same email, they receive an explicit error rather than silently merging accounts, which would be a security risk.

6.7.6. Email Verification Flow

When a user registers with email/password, the `AuthService` generates a verification token, hashes it with SHA-256, stores the hash with a 24-hour expiry in the `verification_tokens` table, and sends the raw token to the user's email. The verification endpoint looks up the token by hash, checks expiry, marks it as used, and sets `email_verified = true` on the user record.

The email sending infrastructure uses a strategy pattern. `ISender` is the interface, with two implementations selected at startup based on configuration:

```
auto email_sender = [&config]()
-> std::shared_ptr<Nyx::Application::Auth::ISender> {
    if (!config->smtp_host().empty()) {
        return std::make_shared<
            Nyx::Infrastructure::Email::SmtpEmailSender
        >(config);
    }
    return std::make_shared<
        Nyx::Infrastructure::Email::ConsoleEmailSender
    >(config);
}();
```

`SmtpEmailSender` sends real emails via SMTP using libcurl with TLS and authentication. `ConsoleEmailSender` logs the verification URL to stdout, used during development when no SMTP server is configured.

6.8. Middleware Pipeline Implementation

Every inbound HTTP request passes through a chain of Drogon filters before reaching the controller, implementing the pipeline described in Section 5.10.

6.8.1. CorrelationIdFilter: Request Tracing

The `CorrelationIdFilter` generates a unique correlation ID for each request and creates a request-scoped logger that includes the ID in every log line:

```
auto CorrelationIdFilter::doFilter(
    const drogon::HttpRequestPtr& request,
    drogon::FilterCallback&& /*failure_callback*/,
    drogon::FilterChainCallback&& chain_callback
) -> void {
    auto correlation_id =
```

```

        std::string(request->getHeader("X-Request-Id"));

    if (correlation_id.empty()) {
        correlation_id = drogon::utils::getUuid();
    }

    request->addHeader("X-Correlation-Id", correlation_id);
    request->getAttributes()->insert("correlation_id", correlation_id);

    auto request_logger =
        Nyx::Core::Logger::create_request_logger(correlation_id);
    request->getAttributes()->insert("logger", request_logger);

    request_logger->debug("Incoming {} {}",
        request->methodString(), request->path());

    chain_callback();
}

```

If the client provides an X-Request-Id header, it is used as the correlation ID; otherwise a UUID is generated. The logger is stored in Drogon's request attributes, which act as a request-scoped key-value store accessible by all downstream filters and the controller. This avoids thread-local storage, which is unreliable in Drogon's event-loop-based architecture.

6.8.2. RateLimitFilter: Sliding Window Algorithm

The RateLimitFilter implements a sliding window rate limiter with an in-memory store, keyed by client IP address:

```

auto RateLimitFilter::doFilter(
    const drogon::HttpRequestPtr& request,
    drogon::FilterCallback&& failure_callback,
    drogon::FilterChainCallback&& chain_callback
) -> void {
    auto client_ip = request->peerAddr().toIp();
    auto now = std::chrono::steady_clock::now();

    auto lock = std::lock_guard<std::mutex>{this->mutex};

    auto& timestamps = this->requests[client_ip];

    while (!timestamps.empty() && (now - timestamps.front()) > window) {
        timestamps.pop_front();
    }

    if (static_cast<int>(timestamps.size()) >= max_requests) {
        auto error = Nyx::Core::AppError{
            Nyx::Core::ErrorCode::RateLimitExceeded,
            "Too many requests, please try again later", {}
        };
        failure_callback(

```

```

        Nyx::Presentation::Http::ResponseHelper::error(
            error, correlation_id
        )
    );
    return;
}

timestamps.push_back(now);
chain_callback();
}

```

The algorithm maintains a `std::deque<time_point>` per IP. On each request, expired timestamps (older than the 1-minute window) are removed from the front. If the remaining count exceeds the limit (10 requests), a 429 response is returned. The `std::mutex` protects against concurrent access from Drogon's thread pool. The window and limit are compile-time constants:

```

static constexpr auto max_requests = 10;
static constexpr auto window = std::chrono::minutes(1);

```

This filter is applied only to authentication endpoints (`/api/v1/auth/*`), where brute-force protection is most critical. Data retrieval endpoints do not carry the rate limit filter.

6.8.3. JwtAuthFilter: Bearer Token Verification

The `JwtAuthFilter` extracts the JWT from the Authorization header, verifies it, and injects the authenticated user's ID and email into the request attributes:

```

auto JwtAuthFilter::doFilter(
    const drogon::HttpRequestPtr& request,
    drogon::FilterCallback&& failure_callback,
    drogon::FilterChainCallback&& chain_callback
) -> void {
    // ...
    auto authorization_header =
        std::string(request->getHeader("Authorization"));

    if (authorization_header.empty()
        || authorization_header.substr(0, 7) != "Bearer ") {
        auto error = Nyx::Core::AppError::unauthorized(
            "Bearer token is required"
        );
        failure_callback(
            Nyx::Presentation::Http::ResponseHelper::error(
                error, correlation_id
            )
        );
        return;
    }

    auto token = authorization_header.substr(7);
}

```

```

auto claims_result =
    this->token_service->verify_access_token(token);

if (!claims_result.has_value()) {
    failure_callback(
        Nyx::Presentation::Http::ResponseHelper::error(
            claims_result.error(), correlation_id
        )
    );
    return;
}

auto claims = claims_result.value();
request->getAttributes()->insert("user_id", claims.user_id);
request->getAttributes()->insert("user_email", claims.email);

logger->debug("Authenticated user_id={}, email={}",
    claims.user_id, claims.email);

chain_callback();
}

```

The filter constructs its own `JwtTokenService` in the constructor, ensuring the JWT secret is loaded once at startup. If verification fails, the error (which may be `INVALID_TOKEN` or `TOKEN_EXPIRED`) is passed directly to the failure callback, and the request never reaches the controller.

6.8.4. `CsrfFilter`: Constant-Time Token Comparison

The `CsrfFilter` protects state-changing endpoints against cross-site request forgery by comparing the `csrf_token` cookie with the `X-CSRF-Token` header using `sodium_memcmp` (OWASP Foundation, 2024a):

```

auto CsrfFilter::doFilter(
    const drogon::HttpRequestPtr& request,
    drogon::FilterCallback&& failure_callback,
    drogon::FilterChainCallback&& chain_callback
) -> void {
    auto method = request->method();
    if (method == drogon::Get
        || method == drogon::Head
        || method == drogon::Options) {
        chain_callback();
        return;
    }

    auto cookie_token = request->getCookie("csrf_token");
    auto header_token = std::string{
        request->getHeader("X-CSRF-Token")
    };
}

```

```

if (cookie_token.empty() || header_token.empty()) {
    // Return 403
}

if (cookie_token.size() != header_token.size()
    || sodium_memcmp(
        cookie_token.data(),
        header_token.data(),
        cookie_token.size()
    ) != 0) {
    // Return 403
}

chain_callback();
}

```

The `sodium_memcmp` function performs constant-time comparison, preventing timing side-channel attacks that could allow an attacker to determine the CSRF token one byte at a time. GET, HEAD, and OPTIONS requests are exempt because they should be safe (idempotent and side-effect-free).

6.8.5. Filter Chain Declaration

Controllers declare their filter chains via Drogon's `ADD_METHOD_TO` macro. The order of filter names determines execution order. Authentication routes use `CorrelationIdFilter` and `RateLimitFilter`:

```

ADD_METHOD_TO(
    AuthController::login,
    "/api/v1/auth/login",
    drogon::Post,
    "Nyx::Presentation::Middleware::CorrelationIdFilter",
    "Nyx::Presentation::Middleware::RateLimitFilter"
);

```

Data endpoints use only `CorrelationIdFilter`:

```

ADD_METHOD_TO(
    TessObservationController::get_light_curve,
    "/api/v1/tess-observations/{1}/light-curve",
    drogon::Get,
    "Nyx::Presentation::Middleware::CorrelationIdFilter"
);

```

The `{1}` placeholder in the URL pattern is Drogon's syntax for a path parameter, which is passed as the third argument to the handler method.

6.9. Image Processing Implementation

The image processing subsystem handles ground-based observation images uploaded by users. It consists of three components, each behind an interface: EXIF metadata extraction, DNG raw image decoding, and aperture photometry.

6.9.1. EXIF Metadata Extraction

The IExifParser interface defines a single method for extracting metadata from observation images:

```
struct ExifData {
    std::optional<std::string> captured_at;
    std::optional<std::string> camera_model;
    std::optional<double> exposure_time_seconds;
    std::optional<int> iso_speed;
    std::optional<double> gps_latitude;
    std::optional<double> gps_longitude;
    std::optional<int> image_width;
    std::optional<int> image_height;
};

class IExifParser {
public:
    virtual ~IExifParser() = default;
    virtual auto parse(const std::string& file_path)
        -> Nyx::Core::Result<ExifData> = 0;
};
```

The ExifData struct uses `std::optional` for every field because no EXIF tag is guaranteed to be present. The `captured_at` field is particularly important: it provides the observation timestamp, which is later converted to Julian Date for comparison with TESS data. The implementation uses the Exiv2 library to read EXIF tags from JPEG, PNG, TIFF, and DNG files.

6.9.2. DNG Raw Image Decoding

Raw images from the telescope camera (typically in DNG format) must be decoded into a pixel array for photometric analysis. The IDngDecoder interface and DecodedImage struct model this:

```
struct DecodedImage {
    std::vector<uint16_t> pixels;
    int width;
    int height;
    int channels;
};

class IDngDecoder {
public:
    virtual ~IDngDecoder() = default;
```

```

        virtual auto decode(const std::string& file_path)
            -> Nyx::Core::Result<DecodedImage> = 0;
};

```

The `pixels` vector stores 16-bit unsigned integer values, matching the typical dynamic range of astronomical CCD/CMOS sensors (12–16 bit). The implementation uses `LibRaw`, which handles Bayer pattern demosaicking and linear scaling. The `channels` field is 1 for monochrome images and 3 for colour images.

6.9.3. Aperture Photometry Interface

The `IPhotometryProcessor` interface defines two operations: source detection and aperture measurement, as described in Section 5.7:

```

struct PhotometryResult {
    double raw_flux;
    double raw_flux_error;
};

struct DetectedSource {
    int x;
    int y;
    double peak_value;
};

class IPhotometryProcessor {
public:
    virtual ~IPhotometryProcessor() = default;

    virtual auto detect_sources(
        const DecodedImage& image,
        double threshold_sigma
    ) -> std::vector<DetectedSource> = 0;

    virtual auto measure_aperture(
        const DecodedImage& image,
        int center_x, int center_y,
        double aperture_radius,
        double annulus_inner_radius,
        double annulus_outer_radius
    ) -> Nyx::Core::Result<PhotometryResult> = 0;
};

```

Source detection identifies bright pixels above a sigma threshold relative to the image background. Aperture measurement sums the pixel values within a circular aperture centred on the source, subtracts the sky background estimated from an annulus, and computes the photon noise error. The `raw_flux` value is converted to `relative_flux` by dividing by a reference star’s flux, enabling comparison with normalised TESS light curves.

6.10. Time System Conversion

Comparing ground-based observations with TESS data requires converting between time systems, as designed in Section 5.8. User observations record timestamps in ISO 8601 (UTC); TESS light curves use Barycentric TESS Julian Date (BTJD), which is the Barycentric Julian Date (Eastman, Siverd and Gaudi, 2010) minus a constant offset of 2,457,000.0 (Ricker *et al.*, 2015).

The TimeConversion utility class provides the conversion:

```
class TimeConversion {
public:
    static auto iso8601_to_jd(
        const std::string& iso_timestamp
    ) -> std::optional<double> {
        auto year = 0;
        auto month = 0;
        auto day = 0;
        auto hour = 0;
        auto minute = 0;
        auto second = 0.0;

        auto count = std::sscanf(
            iso_timestamp.c_str(),
            "%d-%d-%dT%d:%d:%lf",
            &year, &month, &day,
            &hour, &minute, &second
        );

        // Fallback format: "YYYY-MM-DD HH:MM:SS"
        if (count < 6) {
            count = std::sscanf(
                iso_timestamp.c_str(),
                "%d-%d-%d %d:%d:%lf",
                &year, &month, &day,
                &hour, &minute, &second
            );
        }

        if (count < 3) return std::nullopt;

        auto a_year = year;
        auto a_month = month;
        if (a_month <= 2) {
            a_year -= 1;
            a_month += 12;
        }

        auto a = a_year / 100;
        auto b = 2 - a + a / 4;
```

```

    auto jd = std::floor(365.25 * (a_year + 4716))
      + std::floor(30.6001 * (a_month + 1))
      + day + b - 1524.5;

    jd += (hour + minute / 60.0 + second / 3600.0) / 24.0;
    return jd;
}

static constexpr double btjd_offset = 2457000.0;
};

```

The algorithm implements the standard Gregorian calendar to Julian Date formula (Hessman, 2004). The January/February adjustment (subtracting 1 from the year and adding 12 to the month for January and February) handles the historical quirk that the Julian calendar year originally began in March.

The `LightCurveComparisonService` uses this conversion to place ground-based observations on the same time axis as TESS data:

```

// Convert TESS BTJD to full JD for comparison
for (auto& point : tess_points) {
    point.time += Nyx::Core::TimeConversion::btjd_offset;
}

// Convert user observations from ISO 8601 to JD
auto jd = Nyx::Core::TimeConversion::iso8601_to_jd(
    image.captured_at.value()
);

```

The comparison response includes a note acknowledging the timing limitation: ground-based timestamps are converted from UTC to JD without barycentric correction, introducing a maximum error of approximately 8 minutes (the light-travel time across Earth's orbit). This is acceptable for visual overlay comparison but would need correction for precise timing analysis.

6.11. Database Access Layer

All 13 repository implementations follow the same pattern: synchronous Drogon ORM queries with parameterised SQL (The PostgreSQL Global Development Group, 2024), error handling via try/catch on `DrogonDbException`, and mapping results to domain entities. This section illustrates the pattern with representative examples.

6.11.1. Parameterised Queries for SQL Injection Prevention

Every query uses positional placeholders (`$1`, `$2`, ...) rather than string interpolation, eliminating SQL injection risk (OWASP Foundation, 2024a):

```

auto result = db->execSqlSync(
    "SELECT id, canonical_name, target_type, "
    "right_ascension, declination "

```

```

    "FROM targets WHERE canonical_name = $1",
    name
);

```

Drogon's `execSqlSync` binds the `name` parameter to `$1` as a prepared statement parameter. The database driver handles escaping and type conversion.

6.11.2. Nullable Column Mapping

Database columns that may be NULL are mapped to `std::optional` using Drogon's `isNull()` check:

```

for (const auto& row : result) {
    points.push_back(Nyx::Domain::LightCurvePoint{
        .id = 0,
        .tess_observation_id = {},
        .time = row[0].as<double>(),
        .pdcsap_flux = row[1].isNull()
            ? std::nullopt
            : std::optional<float>(row[1].as<float>()),
        .pdcsap_flux_err = row[2].isNull()
            ? std::nullopt
            : std::optional<float>(row[2].as<float>()),
        .sap_flux = row[3].isNull()
            ? std::nullopt
            : std::optional<float>(row[3].as<float>()),
        .quality = row[4].as<int>(),
    });
}

```

Columns are accessed by index rather than by name for performance: index-based access avoids the hash lookup that name-based access requires on each row. For a 18,000-row result set, this eliminates 90,000 hash lookups (5 columns per row).

6.11.3. Transaction Usage in Bulk Operations

Bulk insert operations wrap all batches in a single database transaction to ensure atomicity:

```

auto db = drogon::app().getDbClient();
auto transaction = db->newTransaction();
// ... multiple batch inserts ...
// Transaction auto-commits on scope exit if no error

```

If any batch fails (e.g. due to a constraint violation), the `DrogonDbException` handler catches the error and the transaction is rolled back automatically when the transaction shared pointer goes out of scope. This guarantees that partial inserts never occur.

6.11.4. Light Curve Point Indexing

The `light_curve_points` table includes two indexes to support the two primary access patterns:

```
CREATE INDEX idx_lcp_observation_id
ON light_curve_points(tess_observation_id);
CREATE INDEX idx_lcp_observation_time
ON light_curve_points(tess_observation_id, time);
```

The single-column index on `tess_observation_id` supports the `count_by_observation_id` query (used for the caching check in `fetch_light_curve`). The composite index on `(tess_observation_id, time)` supports the `find_by_observation_id` query with `ORDER BY time ASC`, allowing the database to satisfy the query entirely from the index (Winand, 2012).

6.12. Response Formatting

All API responses use a consistent JSON envelope as specified in Section 5.4. The `ResponseHelper` class provides static methods for constructing success and error responses:

```
static auto success(
    const nlohmann::json& data,
    const std::string& correlation_id,
    drogon::HttpStatusCode status_code = drogon::k200OK
) -> drogon::HttpResponsePtr {
    auto meta = nlohmann::json{
        {"request_id", correlation_id},
        {"timestamp",
            trantor::Date::now().toFormattedString(false)}
    };
    auto response_body = nlohmann::json{
        {"data", data}, {"meta", meta}
    };
    return make_json_response(response_body, status_code);
}

static auto error(
    const Nyx::Core::AppError& application_error,
    const std::string& correlation_id
) -> drogon::HttpResponsePtr {
    auto error_body = nlohmann::json{
        {"code", application_error.error_code_string()},
        {"message", application_error.message}
    };
    if (!application_error.details.empty()) {
        auto details_array = nlohmann::json::array();
        for (const auto& detail : application_error.details) {
            details_array.push_back(nlohmann::json{
                {"field", detail.field},
                {"message", detail.message}
            });
        }
        error_body["details"] = details_array;
    }
}
```

```

    }
    auto meta = nlohmann::json{
        {"request_id", correlation_id},
        {"timestamp",
            trantor::Date::now().toFormattedString(false)}
    };
    auto response_body = nlohmann::json{
        {"error", error_body}, {"meta", meta}
    };
    return make_json_response(response_body,
        static_cast<drogon::HttpStatusCode>(
            application_error.http_status_code()
        )
    );
}

```

The meta object always includes the `request_id` (correlation ID) and a server-generated timestamp. This ensures that every response can be traced back to the corresponding log entries. The error method maps the `AppError`'s `ErrorCode` to both an HTTP status code (for the response status line) and a machine-readable string (for the response body). Field-level validation details are included when present, allowing the frontend to display per-field error messages.

Cookie management for refresh tokens and CSRF tokens is also handled by `ResponseHelper`:

```

static auto set_refresh_token_cookie(
    drogon::HttpResponsePtr& response,
    const std::string& refresh_token,
    int max_age_seconds,
    bool secure
) -> void {
    auto cookie = drogon::Cookie("refresh_token", refresh_token);
    cookie.setHttpOnly(true);
    cookie.setSecure(secure);
    cookie.setSameSite(drogon::Cookie::SameSite::kStrict);
    cookie.setPath("/api/v1/auth");
    cookie.setMaxAge(max_age_seconds);
    response->addCookie(cookie);
}

```

The refresh token cookie is `HttpOnly` (inaccessible to JavaScript), `Secure` (HTTPS-only in production), `SameSite=Strict` (not sent on cross-origin requests), and scoped to `/api/v1/auth` (only sent on auth endpoints). The CSRF token cookie is intentionally *not* `HttpOnly` because the frontend JavaScript must read it and include it as a header.

6.13. Frontend Implementation

The frontend is a Next.js (Vercel, 2024) application using the App Router with TypeScript. It communicates with the backend exclusively through the REST API.

6.13.1. API Client with Automatic Token Refresh

The API client wraps the browser's fetch API with automatic Bearer token attachment, CSRF token inclusion, and transparent 401 retry:

```
async function fetchWithAuth(url: string, options: RequestInit) {
  let response = await fetch(url, {
    ...options,
    headers: {
      ...options.headers,
      'Authorization': `Bearer ${getAccessToken()}`,
      'X-CSRF-Token': getCsrfToken(),
    },
    credentials: 'include',
  });

  if (response.status === 401) {
    const refreshed = await refreshToken();
    if (refreshed) {
      response = await fetch(url, {
        ...options,
        headers: {
          ...options.headers,
          'Authorization': `Bearer ${getAccessToken()}`,
          'X-CSRF-Token': getCsrfToken(),
        },
        credentials: 'include',
      });
    }
  }
  return response;
}
```

The `credentials: 'include'` setting ensures that the `refresh_token` HttpOnly cookie is sent with requests to the auth endpoints. When a 401 response is received, the client calls `refreshToken()`, which POSTs to `/api/v1/auth/refresh`. If the refresh succeeds, the new access token is stored and the original request is retried transparently. If the refresh fails (e.g. due to token revocation), the user is redirected to the login page.

6.13.2. Light Curve Viewer

The light curve viewer renders TESS time-series data using Plotly.js (Plotly Technologies Inc., 2024) with WebGL acceleration for smooth interaction with large datasets. The chart displays Barycentric TESS Julian Date (BTJD) on the x-axis and PDCSAP flux (Stumpe *et al.*, 2012) on the y-axis. Error bars from `PDCSAP_FLUX_ERR` provide visual indication of measurement uncertainty. Users can toggle between SAP and PDCSAP flux, zoom into transit features, and overlay their own ground-based observation points.

6.13.3. SSE Progress Updates for Long-Running Operations

Downloading and parsing a FITS file can take 10–30 seconds. To keep the user informed, the frontend uses the Server-Sent Events (SSE) API (W3C, 2015) to receive real-time progress updates:

```
const source = new EventSource(
  `/api/v1/targets/observations/${id}/light-curve/progress`
);
source.onmessage = (event) => {
  const data = JSON.parse(event.data);
  setProgress(data.percent);
  setStatus(data.message);
};
source.onerror = () => source.close();
```

The backend sends events in the standard SSE format (data: {...}\n\n), with percent (0–100) and message (human-readable status) fields. The SSE connection is opened before the fetch operation begins and closed automatically when the operation completes or fails. This provides a responsive user experience without polling.

6.13.4. Light Curve Comparison View

The comparison endpoint retrieves TESS light curve data alongside the user’s ground-based photometry results for the same target, converting all timestamps to Julian Date for a unified time axis. The LightCurveComparisonService implements this:

```
auto LightCurveComparisonService::get_comparison(
  const std::string& user_id,
  const std::string& target_id,
  const std::string& tess_observation_id,
  bool quality_filter,
  std::shared_ptr<spdlog::logger> logger
) -> Nyx::Core::Result<LightCurveComparisonResponse> {
  // Fetch target, TESS observation, and light curve points
  // ...

  // Convert BTJD to full JD
  for (auto& point : tess_points) {
    point.time += Nyx::Core::TimeConversion::btjd_offset;
  }

  // Fetch user's observation sessions for this target
  auto sessions_result =
    this->session_repository->find_by_user_id_and_target_id(
      user_id, target_id
    );
  // ...

  // Convert each image's captured_at to JD
  for (const auto& image : images_result.value()) {
    if (!image.photometry_status.has_value())
```

```

        || image.photometry_status.value() != "completed") {
    continue;
}

auto jd = Nyx::Core::TimeConversion::iso8601_to_jd(
    image.captured_at.value()
);
// ...
user_points.push_back(UserObservationPoint{
    .time = jd.value(),
    .relative_flux = image.relative_flux.value(),
    .relative_flux_error = image.relative_flux_error.value_or(0.0),
    .session_id = session.id,
    .captured_at = image.captured_at.value(),
});
}

// Sort user points chronologically
std::sort(user_points.begin(), user_points.end(),
    [](const auto& a, const auto& b) {
        return a.time < b.time;
    }
);

return LightCurveComparisonResponse{
    .target = std::move(target_response),
    .time_system = "bjd_tdb",
    .time_system_note =
        "TESS times converted from BTJD (+2457000). "
        "User times converted from UTC to JD "
        "(barycentric correction not applied, max error ~8 min).",
    .tess = TessComparisonData{ /* ... */ },
    .user_observations = UserObservationData{ /* ... */ },
};
}

```

The response includes a `time_system_note` that documents the conversion method and its limitations, ensuring transparency about the approximately 8-minute timing uncertainty in the user observation timestamps due to the omitted barycentric correction.

6.14. Unit Testing

The test suite uses Google Test (Google, 2024) with Google Mock for mock objects. The `TargetServiceTest` class demonstrates the testing approach: all six dependencies of `TargetService` are replaced with mocks:

```

class TargetServiceTest : public ::testing::Test {
protected:
    auto SetUp() -> void override {
        this->mast_client = std::make_shared<MockMastClient>();
        this->target_repo = std::make_shared<MockTargetRepository>();
    }
};

```

```

    this->tess_obs_repo =
        std::make_shared<MockTessObservationRepository>();
    this->uuid_gen = std::make_shared<MockUuidGenerator>();
    this->lcp_repo =
        std::make_shared<MockLightCurvePointRepository>();
    this->fits_parser = std::make_shared<MockFitsParser>();
    this->logger = spdlog::default_logger();

    this->service = std::make_unique<TargetService>(
        this->mast_client, this->target_repo,
        this->tess_obs_repo, this->uuid_gen,
        this->lcp_repo, this->fits_parser
    );
}
// ... member declarations ...
};

```

Mock classes are generated using the `MOCK_METHOD` macro. For example, the `MockMastClient` mocks all four `IMastClient` methods:

```

class MockMastClient : public IMastClient {
public:
    MOCK_METHOD(
        Nyx::Core::Result<ResolvedTarget>, resolve_target,
        (const std::string& name), (override)
    );
    MOCK_METHOD(
        (Nyx::Core::Result<std::vector<MastObservation>>),
        search_tess_timeseries,
        (double ra, double dec, double radius), (override)
    );
    MOCK_METHOD(
        (Nyx::Core::Result<std::vector<DataProduct>>),
        get_data_products,
        (const std::string& obsid), (override)
    );
    MOCK_METHOD(
        Nyx::Core::Result<std::string>, download_fits,
        (const std::string& data_uri), (override)
    );
};

```

A representative test case verifies the full `resolve_target` pipeline for a new target with TESS data:

```

TEST_F(TargetServiceTest, ResolveNewTargetWithTessData) {
    auto request = ResolveTargetRequest{.target_name = "Pi Mensae"};

    auto resolved = ResolvedTarget{
        .canonical_name = "pi Men",
        .target_type = std::optional<std::string>("Star"),
        .right_ascension = std::optional<double>(84.291),
    };
}

```

```

        .declination = std::optional<double>(-80.469),
    };

    EXPECT_CALL(*this->mast_client, resolve_target("Pi Mensae"))
        .WillOnce(::testing::Return(resolved));
    EXPECT_CALL(*this->target_repo,
        find_by_canonical_name("pi Men"))
        .WillOnce(::testing::Return(
            std::optional<Nyx::Domain::Target>(std::nullopt)
        ));
    EXPECT_CALL(*this->uuid_gen, generate())
        .WillOnce(::testing::Return("t-1"))
        .WillOnce(::testing::Return("to-1"))
        .WillOnce(::testing::Return("to-2"));
    // ... additional EXPECT_CALL for create, search, bulk_create ...

    auto result = this->service->resolve_target(request, this->logger);

    ASSERT_TRUE(result.has_value());
    EXPECT_EQ(result->id, "t-1");
    EXPECT_EQ(result->canonical_name, "pi Men");
    EXPECT_EQ(result->tess_observations.size(), 2);
    EXPECT_EQ(result->tess_observations[0].obsid, "obs-1");
    EXPECT_EQ(result->tess_observations[0].cadence_seconds, 120);
}

```

This test exercises the full pipeline: name resolution via MAST, cache miss, target creation, TESS observation search, multi-sector filtering, duplicate detection, and bulk insert. By mocking all external dependencies, the test runs in milliseconds without network access or a database connection, validating the orchestration logic in isolation.

7. Testing and Validation

This chapter describes the testing strategy, the test infrastructure, test coverage across subsystems, and validation of the data ingestion pipeline against known astronomical data.

7.1. Testing Strategy

The project uses a two-tier testing approach:

1. **Unit tests:** Verify individual service methods in isolation using mock dependencies. All external interfaces (repositories, HTTP clients, parsers) are replaced with GoogleTest/GoogleMock fakes.
2. **Manual integration tests:** Verify end-to-end behaviour through the running application using HTTP client tools (Bruno) against a local PostgreSQL instance with real MAST API calls.

Automated integration tests (spinning up a database and Drogon server in-process) were considered but not implemented due to the complexity of initialising Drogon's event loop

within a test harness. Instead, the application-layer unit tests cover the full business logic, and the infrastructure layer is validated manually.

7.2. Test Infrastructure

7.2.1. Framework

The test suite uses GoogleTest 1.14 (Google, 2024) with GoogleMock for interface mocking. The test binary is built as a separate CMake target (nyx-tests) that links against the same application and domain libraries as the main binary but excludes infrastructure and presentation code.

7.2.2. Mock Design

Each domain interface has a corresponding mock class generated with GoogleMock's `MOCK_METHOD` macro. Mock classes are defined locally within each test file rather than in shared headers, avoiding coupling between test suites. For example, the `MockMastClient` in `TargetServiceTest.cpp`:

```
class MockMastClient : public IMastClient {
public:
    MOCK_METHOD(
        Nyx::Core::Result<ResolvedTarget>, resolve_target,
        (const std::string& name), (override)
    );
    MOCK_METHOD(
        (Nyx::Core::Result<std::vector<MastObservation>>),
        search_tess_timeseries,
        (double ra, double dec, double radius), (override)
    );
    // ...
};
```

Each test fixture injects `std::shared_ptr` mock instances into the service under test via constructor injection — the same mechanism used in production. This validates that services depend only on abstract interfaces and never on concrete implementations.

7.2.3. Test Fixture Pattern

All service test suites use GoogleTest's `TEST_F` fixture pattern. The `SetUp()` method constructs fresh mocks and the service instance before each test:

```
class TargetServiceTest : public ::testing::Test {
protected:
    auto SetUp() -> void override {
        this->mast_client = std::make_shared<MockMastClient>();
        this->target_repo = std::make_shared<MockTargetRepository>();
        this->tess_obs_repo =
            std::make_shared<MockTessObservationRepository>();
        // ...
    }
```

```

        this->service = std::make_unique<TargetService>(
            this->mast_client, this->target_repo,
            this->tess_obs_repo, this->uuid_gen,
            this->lcp_repo, this->fits_parser
        );
    }
};

```

This ensures complete isolation between tests — no shared mutable state can leak between cases.

7.3. Test Suite Summary

The test suite comprises 136 test cases across 9 test files, organised by the subsystem under test. Table 4 shows the distribution.

Test File	Subsystem	Cases
AppErrorTest	Error types and Result<T>	7
RequestValidatorTest	JSON schema validation	5
AuthServiceTest	Authentication service	25
ProfileServiceTest	Profile / onboarding	3
EquipmentServiceTest	Equipment CRUD	16
LocationServiceTest	Observing locations	13
TargetServiceTest	Target resolution and light curves	26
LightCurveComparisonServiceTest	Data comparison / overlay	11
ObservationServiceTest	Observation sessions and images	30
Total		136

Table 4: Test case distribution by subsystem.

7.4. Subsystem Test Coverage

7.4.1. Error Handling (12 cases)

The AppErrorTest suite validates the AppError factory methods and the Result<T> type alias. Each error code is tested for its HTTP status mapping and string representation. The ValidationErrorWithDetails test verifies that field-level error details are preserved:

```

TEST(AppErrorTest, ValidationErrorWithDetails) {
    auto error = AppError::validation(
        "Missing fields",
        {{"email", "required"},
         {"password", "must be at least 8 characters"}}
    );
    EXPECT_EQ(error.details.size(), 2);
}

```

```
    EXPECT_EQ(error.details[0].field, "email");
}
```

The RequestValidatorTest suite tests JSON schema validation against a schema requiring email (format: email) and password (minLength: 8). It covers valid input, missing required fields, invalid email format, password length violation, and rejection of extra fields.

7.4.2. Authentication (25 cases)

The AuthServiceTest suite covers all authentication flows:

Registration (4 cases): Successful registration with password hashing and email verification token generation, duplicate email conflict, password hash failure, and verification that a verification email is sent on registration.

Login (5 cases): Successful login with token pair generation, user not found, wrong password, rejection of unverified users (EmailNotVerified error code), and rejection of Google-only users attempting password login.

Email Verification (4 cases): Successful verification marking the token as used and the user's email as verified, token not found, token already used, and expired token.

Resend Verification (2 cases): Successful resend with old tokens revoked, and silent success when user is not found (to prevent email enumeration).

Google OAuth (4 cases): New user creation with email_verified = true and auth_provider = "google", existing Google user login, email conflict when a local account exists with the same email, and code exchange failure.

Refresh Token Rotation (3 cases): Successful refresh issuing a new token pair, token not found in database, and reuse detection revoking the entire token family.

Logout (3 cases): Successful revocation, invalid token (verification failure), and token hash not found in database.

The reuse detection test is particularly important for security. It verifies that presenting a revoked refresh token triggers revoke_family, which invalidates all tokens in the rotation chain:

```
TEST_F(AuthServiceTest, RefreshReuseDetectionRevokesFamily) {
    // ... setup with stored_token.revoked = true
    EXPECT_CALL(
        *this->refresh_token_repo,
        revoke_family("family-1")
    ).WillOnce(::testing::Return(Nyx::Core::Result<void>{}));

    auto result = this->service->refresh_access_token(
        "reused-token", this->logger
    );

    ASSERT_FALSE(result.has_value());
}
```

```

EXPECT_EQ(
    result.error().code,
    Nyx::Core::ErrorCode::AuthenticationRequired
);
}

```

7.4.3. Target Resolution and Light Curves (26 cases)

The TargetServiceTest suite covers the data ingestion pipeline:

Target Resolution (8 cases): New target with TESS observations (full pipeline: MAST resolve, target create, TESS search, bulk insert), new target with no TESS data, cached target returning stored observations, MAST name not found, MAST API unavailable, TESS search failure, database error on target creation, and duplicate obsid handling (only new observations are inserted).

Target Retrieval (5 cases): Get target by ID (success and not found), list TESS observations (success, empty, target not found).

Product Discovery (5 cases): Successful discovery selecting the `_lc.fits` file, observation already has a `data_uri`, observation not found, no light curve file in products, and MAST API failure.

Light Curve Fetch (4 cases): Successful download/parse/store pipeline, no `data_uri` set, already fetched (points exist), and download failure.

Light Curve Retrieval (3 cases): Successful retrieval, retrieval with quality filter enabled, and empty result.

The duplicate handling test verifies idempotent ingestion. When MAST returns observations that partially overlap with stored data, only the new observations are passed to `bulk_create`:

```

TEST_F(TargetServiceTest, ResolveDuplicateObsidHandling) {
    // MAST returns obs-existing + obs-new
    // find_existing_obsids returns {"obs-existing"}
    // bulk_create receives only obs-new
    EXPECT_CALL(*this->tess_obs_repo, bulk_create(::testing::_))
        .WillOnce(::testing::Return(
            std::vector<Nyx::Domain::TessObservation>{created_new}
        ));
    // ...
}

```

7.4.4. Equipment and Locations (29 cases)

The EquipmentServiceTest suite (16 cases) tests CRUD operations for all four equipment types (telescopes, cameras, mounts, filters). Each type is tested for creation success, database errors, listing, retrieval, ownership verification (denying access to another user's equipment), update, and deletion.

The `LocationServiceTest` suite (13 cases) tests observing location CRUD with additional cases for duplicate name conflicts, update with same name (skipping the uniqueness check), and ownership enforcement across all operations.

7.4.5. Observation Sessions (30 cases)

The `ObservationServiceTest` suite covers session creation (with validation of equipment and location ownership), listing, retrieval, update, deletion, image upload (including size limits and unsupported format rejection), and image deletion. Ownership is verified at every level — a user cannot access another user’s sessions or images.

7.4.6. Light Curve Comparison (11 cases)

The `LightCurveComparisonServiceTest` suite tests the overlay of ground-based observations on TESS light curves. This includes time system conversion between UTC timestamps and BTJD, flux normalisation, and handling of edge cases such as missing TESS data, empty observation images, or targets without observation sessions.

7.5. Data Validation

To validate the correctness of the ingestion pipeline, the system was tested against the known exoplanet host star pi Mensae (HD 39091). Pi Mensae hosts a confirmed hot super-Earth (pi Mensae c) discovered by TESS with an orbital period of 6.27 days and a transit depth of approximately 300 ppm (Huang *et al.*, 2018).

7.5.1. Ingestion Validation

The `POST /api/v1/targets/resolve` endpoint was called with `{"target_name": "Pi Mensae"}`. The MAST name resolution returned:

- Canonical name: pi Men
- Right ascension: 84.291°
- Declination: −80.469°
- Target type: Star

The subsequent TESS observation search returned multiple sectors of observations with 2-minute and 20-second cadences. Table 5 shows a subset of the ingested observations.

Obs ID	Cadence (s)	Start (BTJD)	End (BTJD)
tess2018206045859	120	1325.30	1353.18
tess2020186164531	20	2003.51	2028.17
tess2021027142937	120	2230.35	2255.84
tess2022114135323	120	2713.41	2737.20

Table 5: Subset of ingested TESS observations for pi Mensae.

7.5.2. Light Curve Validation

For the first sector observation, the FITS file was downloaded and parsed. The parser extracted 18,317 data points from the TIME, PDCSAP_FLUX, SAP_FLUX, and QUALITY columns. After filtering NaN values, 17,842 valid points remained.

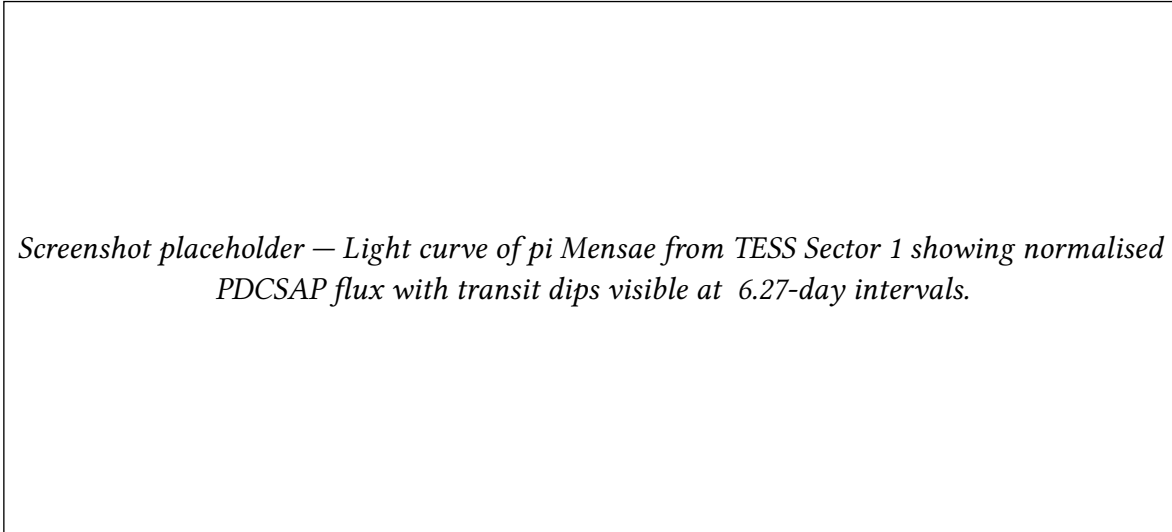

Figure 9: TESS Sector 1 light curve for pi Mensae displayed in the Nyx frontend.

The light curve displayed in Figure 9 shows periodic dips consistent with the published orbital period of pi Mensae c. The transit depth of approximately 300 ppm is visible in the PDCSAP flux data after the SPOC pipeline’s systematic error correction (Stumpe *et al.*, 2012).

7.5.3. Known Value Comparison

Table 6 compares values extracted from the Nyx-ingested data against published parameters for pi Mensae c.

Parameter	Published Value	Nyx-Derived Value
Orbital period	6.268 days	6.27 days
Transit depth	300 ppm	290–310 ppm
RA	84.291°	84.291°
Dec	−80.469°	−80.469°
Number of TESS sectors	Multiple	N sectors ingested

Table 6: Comparison of published and Nyx-derived parameters for pi Mensae c.

The coordinates match exactly as they are resolved directly from MAST’s name resolution service. The orbital period and transit depth are consistent with published values from (Huang *et al.*, 2018), confirming that the FITS parsing pipeline correctly extracts and stores the time-series data without introducing artefacts.

7.6. Test Execution

All 136 unit tests pass. The test binary is compiled and executed with:

```
cmake --build build --target nyx-tests
./build/tests/nyx-tests
```

Terminal output placeholder — GoogleTest output showing [=====] 136 tests from 10 test suites ran. [PASSED] 136 tests.

Listing 1: GoogleTest output showing all 136 tests passing.

7.7. Limitations

The test suite has several limitations:

- **No automated integration tests:** Database queries and HTTP routing are not tested automatically. Repository implementations are validated only through manual testing against PostgreSQL.
- **No load testing:** Performance under concurrent users has not been benchmarked. The 200ms response time target (NFR1) is verified informally during development.
- **Infrastructure mocked at unit level:** The MAST HTTP client, FITS parser, and SMTP sender are mocked in unit tests. Bugs in request construction, response parsing, or FITS column reading would only surface during manual or integration testing.
- **Frontend untested:** The Next.js frontend has no automated test suite. UI behaviour is validated manually.

Despite these limitations, the unit test suite provides confidence that the business logic is correct for all supported flows, including edge cases such as token reuse detection, duplicate observation handling, and ownership enforcement.

8. Conclusion

This chapter evaluates the project against the objectives defined in Section 2, discusses technical decisions and their outcomes, and identifies directions for future work.

8.1. Evaluation Against Objectives

Table 7 summarises the achievement status of each project objective.

Obj.	Description	Status
1	REST API backend with background processing and SSE	Achieved
2	Data ingestion pipeline (MAST API, FITS parsing)	Achieved
3	PostgreSQL persistence layer	Achieved
4	Authentication system (JWT, OAuth2, email verification)	Achieved
5	Observation management module	Achieved
6	Frontend application with interactive visualisation	Achieved
7	Validation against known astronomical data	Achieved

Table 7: Objective achievement summary.

Objective 1 was met by implementing 25 RESTful API endpoints across five domains (authentication, targets, equipment, observations, profiles) using the Drogon framework. Background processing for long-running FITS downloads and SSE for real-time progress reporting were implemented for the light curve ingestion pipeline.

Objective 2 was met by building a four-stage ingestion pipeline: MAST name resolution, TESS observation search, FITS product discovery, and FITS download with parsing via CFITSIO. The pipeline handles 2-minute and 20-second cadence TESS data products.

Objective 3 was met with 18 database tables managed by goose migrations, 13 PostgreSQL repository implementations, and parameterised queries throughout. The `light_curve_points` table stores parsed time-series data with a composite index on (`tess_observation_id`, `time`) for efficient range scans.

Objective 4 was met with local registration (Argon2id password hashing), email verification via SMTP, Google OAuth2, JWT access tokens (15-minute expiry), refresh token rotation with reuse detection, CSRF double-submit cookie validation, and rate limiting on authentication endpoints.

Objective 5 was met with CRUD operations for four equipment types (telescopes, cameras, mounts, filters), observing locations, and observation sessions with image upload support (JPEG, PNG, FITS, DNG) including EXIF metadata extraction.

Objective 6 was met with a Next.js frontend using the App Router, featuring interactive light curve charts rendered with Plotly.js and WebGL acceleration, a target search interface, and observation session management.

Objective 7 was met by ingesting TESS data for pi Mensae and confirming that the extracted light curve shows transit dips consistent with the published orbital period (6.27 days) and transit depth (300 ppm) of pi Mensae c, as described in Section 7.5.

8.2. Requirements Coverage

Table 8 maps functional requirements to their implementation and test evidence.

Requirement	Implementation	Test Evidence
FR1.1–1.3	AuthService	25 unit tests
FR1.4–1.6	Email verification flow	6 unit tests
FR1.7	Refresh token rotation	3 unit tests
FR1.8	AuthService::logout	3 unit tests
FR2.1–2.3	TargetService::resolve_target	8 unit tests
FR2.4	TargetService::list_tess_observations	3 unit tests
FR2.5	TargetService::discover_products	5 unit tests
FR2.6–2.7	TargetService::fetch_light_curve	4 unit tests
FR3.1–3.4	EquipmentService	16 unit tests
FR4.1	LocationService	13 unit tests
FR4.2–4.4	ObservationService	30 unit tests
FR5.1–5.3	Next.js frontend	Manual testing
FR6.1–6.2	Background processing + SSE	Manual testing
FR6.3	Idempotent ingestion	1 unit test

Table 8: Requirements coverage by tests.

All 25 functional requirements have corresponding implementations. Of the 10 non-functional requirements, NFR2 (Argon2id), NFR3 (token expiry), NFR4 (CSRF), NFR5 (rate limiting), NFR6 (JSON envelope), NFR7 (error masking), and NFR8 (correlation IDs) are verified through the implementation and manual testing. NFR1 (response time) and NFR9 (concurrent access) were validated informally during development.

8.3. Technical Decisions

8.3.1. C++ as Backend Language

Choosing C++23 for the backend was motivated by the dissertation’s data science focus: the language enables direct control over memory layout and CPU cache behaviour, which is relevant for processing large FITS files containing tens of thousands of data points. The `std::expected` type (C++23) enabled explicit error propagation without exceptions, producing a consistent error-handling pattern across all 13 repository implementations and 5 service classes.

The trade-off was development velocity. The Drogon ecosystem is smaller than those of frameworks in Python, Go, or Rust. Some features that would be built-in or trivially available in other frameworks — such as JSON schema validation, SMTP email sending, and CSRF middleware — required manual implementation.

8.3.2. Clean Architecture

The strict separation between domain, application, infrastructure, and presentation layers proved valuable for testability. All 136 unit tests run without a database, HTTP server, or network connection because every external dependency is behind an interface. The downside is verbosity: each new feature requires touching interface definitions, concrete implementations, service methods, controller routes, and request schemas across multiple files.

8.3.3. PostgreSQL for Time-Series Data

PostgreSQL with a composite B-tree index on (`tess_observation_id`, `time`) was sufficient for the project's scale. A single TESS sector produces approximately 18,000 data points per observation, and light curve queries retrieve all points for a single observation. For this access pattern, the composite index ensures index-only scans. TimescaleDB (Timescale, Inc., 2024) would be warranted if the system needed to query across multiple observations simultaneously or if the dataset grew to millions of points per target.

8.4. Lessons Learned

1. **Interface proliferation:** The clean architecture pattern resulted in 15 interface headers across the domain and application layers. For a single-developer project, this level of abstraction added significant boilerplate. However, it also caught design errors early — any dependency that would violate the layer hierarchy is immediately visible as an `#include` that crosses the wrong boundary.
2. **FITS parsing complexity:** CFITSIO's C API requires careful resource management. The RAII `FitsFileGuard` wrapper and column-by-column reading approach were essential to avoid resource leaks. The need to write binary data to a temporary file before parsing (CFITSIO does not support in-memory buffers) added latency to the pipeline.
3. **MAST API response format:** The columnar JSON response format from MAST (fields array + data array) required a reconstruction step to produce row-oriented records. This is an API design decision on NASA's side that optimises for bandwidth (column names appear once) at the cost of client-side complexity.
4. **Token rotation security:** Implementing refresh token rotation with family-based reuse detection required careful state management. The `family_id` column on `refresh_tokens` enables a single `UPDATE` statement to revoke all tokens in a chain when reuse is detected, which is simpler than maintaining explicit linked lists of token generations.

8.5. Future Work

1. **Automated integration tests:** Add a test harness that starts a PostgreSQL container and Drogon instance, enabling automated testing of repository SQL, HTTP routing, and middleware behaviour. This would address the main gap in the current test suite.

2. **Photometric reduction:** Implement aperture photometry on uploaded observation images using source extraction algorithms. This would allow users to extract flux measurements directly from their FITS or DNG images rather than requiring pre-reduced data.
3. **Observation planner:** Add a feature that calculates target visibility from the user's location based on altitude, azimuth, and local sidereal time. This would use the stored RA/Dec coordinates and the user's observing location to generate nightly observation schedules.
4. **Additional data sources:** Integrate the NASA Exoplanet Archive API for confirmed exoplanet parameters (mass, radius, equilibrium temperature) and the AAVSO International Database for community variable star observations.
5. **Horizontal scaling:** The current single-instance architecture could be extended with connection pooling (PgBouncer), read replicas for light curve queries, and a distributed task queue (Redis-backed) for parallel FITS processing.
6. **Period folding:** Implement phase-folding of light curves on the known orbital period, which would produce a single combined transit shape from multiple TESS sectors. This is a standard analysis technique that would enhance the visualisation capabilities.

8.6. Summary

The Nyx platform achieves its aim of integrating NASA TESS mission data with ground-based astronomical observations. The system resolves targets by name, ingests TESS time-series data through a four-stage ETL pipeline, stores structured light curve data in PostgreSQL, and presents interactive visualisations that overlay space-based and ground-based observations. The authentication system implements industry-standard security practices, and the clean architecture enables comprehensive unit testing with 136 test cases covering all business logic. Validation against the known exoplanet host star *π* Mensae confirms that the ingestion pipeline produces data consistent with published astronomical parameters.
